In young children, *M. pneumoniae* can be indistinguishable from viral causes of respiratory tract infection; concomitant *Mycoplasma* and viral infection also occurs.[40–42] *M. pneumoniae* infection in young children can be asymptomatic or associated with rhinorrhea, pharyngitis, otitis media, croup, bronchiolitis, or pneumonia.[11,19,29,43,44] *M. pneumoniae* infection in older children and adolescents causes both upper or lower respiratory tract illness. Initial symptoms typically consist of general malaise, myalgia, sore throat, retrobulbar headache, and fever.[29,45] Sinus pain or fullness and ear pain often are described. These symptoms are indistinguishable from those caused by influenza and other respiratory viruses. Physical findings include sinus tenderness, nonexudative posterior pharyngeal erythema, and otitis media reflecting sites of infection. Although experimental *M. pneumoniae* infection in adults was associated with bullous myringitis,[46] numerous other causes of bullous myringitis have been identified.[47,48] *M. pneumoniae* was not detected by PCR in any of 37 children with either bullous or hemorrhagic myringitis.[49] Additionally, *M. pneumoniae* was isolated from culture of middle ear fluid in only 1 of 771 children with otitis media.[50]

The characteristic course of *M. pneumoniae* pneumonia is depicted in Fig. 196.1. Patients with pneumonia usually have had fever, myalgia, and other constitutional symptoms in the first week of illness that resolves when a dry, nonproductive cough develops; this cough can become productive of mucopurulent or blood-streaked sputum. The cough usually brings the patient to medical attention 5 to 7 days after onset, and it can be paroxysmal and worse at night. Coughing from either *M. pneumoniae* tracheobronchitis or pneumonia can persist for ≥2 weeks after resolution of fever and other constitutional signs and symptoms, thus resulting in a 4-week illness that can resemble pertussis.[50] Palpation of the neck can produce paroxysms of coughing. Auscultation of the chest frequently reveals crackles or wheezes or both, hence the appellation "walking pneumonia." *M. pneumoniae* has been documented to cause parapneumonic effusions and necrotizing pneumonitis in children.[51,53,54] Severe and sometimes fatal *M. pneumoniae* pneumonia is reported in both adults and children.[55–61]

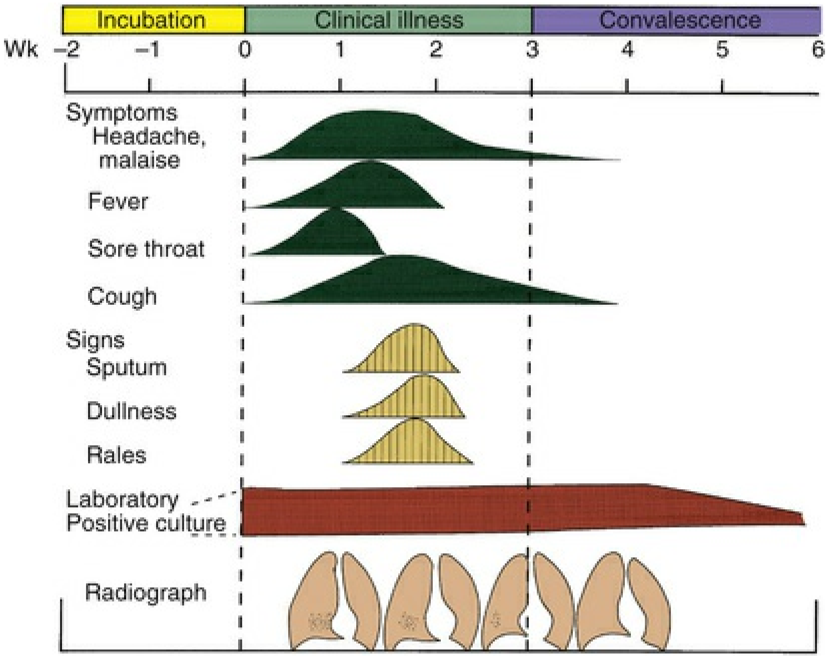

FIGURE 196.1 **Characteristic clinical course of pneumonia caused by *Mycoplasma pneumoniae*.** (Redrawn from Denny FW, Clyde WA Jr, Glezen WP. *Mycoplasma pneumoniae* disease: clinical spectrum, pathophysiology, epidemiology, and control. J Infect Dis 1971;123:74.)

M. pneumoniae infections frequently are associated with exacerbations of asthma. In a prospective study, *M. pneumoniae* was detected by either PCR or serologic study in 20% of children hospitalized for exacerbation of asthma and in 50% of children hospitalized for first-episode wheezing; in contrast, *M. pneumoniae* infection was diagnosed in only 5% of control children with either stable asthma or allergic rhinitis.[62] *M. pneumoniae* also can have a role in chronic lung disease. Mice experimentally inoculated with *M. pneumoniae* into the respiratory tract were more likely than control mice to have chronic pulmonary disease characterized by airway hyperreactivity, airway obstruction, and histologic inflammation.[63] In children, pulmonary abnormalities, including reduced pulmonary clearance and airway hyperresponsiveness, can persist for months to years following *M. pneumoniae* infection.[64,65]

Numerous case reports describe severe respiratory illness caused by *M. pneumoniae* in immunodeficient children. *M. pneumoniae* was detected in 2% of bronchoalveolar lavage specimens from human immunodeficiency virus–infected patients with pneumonia.[66] Serologic evidence of *M. pneumoniae* infection was demonstrated in 9% of 538 children with sickle cell disease and acute chest syndrome.[67] Patients with sickle cell disease or sickle cell–related hemoglobinopathies and Down syndrome often develop severe respiratory illness as a consequence of *M. pneumoniae* infection.[68–71]

Extrapulmonary Disease

Extrapulmonary complications of *M. pneumoniae* infection occur (Table 196.1).[72–98] A causative role is confirmed by PCR detection at extrapulmonary sites, but many reports remain anecdotal, with diagnosis resting on elevation of cold agglutinin or complement fixation (CF) antibody values. Because CF antibodies can cross-react with human tissue, particularly brain and pancreas, antibody elevation can occur during inflammation or destruction of tissue from multiple causes. In the context of family and community outbreaks of *M. pneumoniae* infection, however, and in patients with concomitant pulmonary involvement, reports of extrapulmonary involvement are more credible.[99–102] Additionally, occasional isolation of *M. pneumoniae* from blood, CSF, synovial fluid, and skin lesions (primarily in immunocompromised patients) indicates that dissemination occurs in some cases. PCR testing has confirmed the role of *M. pneumoniae* in isolated cases of encephalitis and transverse myelitis,[8,103–105] pleural effusion,[54] and bacteremia.[9] It remains unclear, however, whether most "*Mycoplasma*-associated" extrapulmonary cases reported are caused by *Mycoplasma* infection or *Mycoplasma*-related immune-mediated mechanisms or are unrelated to *Mycoplasma*.

TABLE 196.1

Extrapulmonary Disease Associated With *Mycoplasma pneumoniae*[a]

Disease by Organ System	Manifestation
Dermatologic disease	Discrete maculopapules
	Erythema multiforme
	Stevens-Johnson syndrome
	Gianotti-Crosti syndrome
	Urticaria
	Morbilliform exanthem
	Vesicles or bullae
	Ulcerative stomatitis
	Erythema marginatum
Hematologic disease or condition	Complement-dependent, Coombs-positive, anti-I antigen, immunoglobulin M antibody
	Thrombosis (transient antiphospholipid antibody response)
	Thrombotic thrombocytopenic purpura
Central nervous system disease	Encephalitis/meningoencephalitis
	Transverse myelitis
	Guillain-Barré syndrome
	Focal encephalitis
	Polyradiculitis
	Bell palsy
	Asymmetric paralysis
	Cerebellar ataxia
	Psychosis
	Cerebral infarction
Arthritis	Acute or chronic course
	Monoarticular, migratory, or polyarticular arthritis
Cardiac disease	Pericarditis
	Myocarditis
	Heart block
	Myocardial infarction
	Congestive heart failure
Hepatic dysfunction	Mild hepatic enzyme elevation[b]
Pancreatitis	Acute inflammation
Ocular disease	Conjunctivitis
	Glomerulonephritis
	Iritis
	Optic disc edema
Other	Rhabdomyolysis

[a] Organ system or finding occurs in <10% of cases except where noted.

[b] Occurs in approximately 30% of cases with pneumonia.

The central nervous system appears to be the most common extrapulmonary site of *M. pneumoniae* disease. Of 1988 patients enrolled in the California Encephalitis Project, 111 (5.6%) had evidence of recent or current *M. pneumoniae* infection.[106] In some series, central nervous system involvement is reported in 1% to 7% of patients requiring hospitalization for *M. pneumoniae* infection.[79,107,108] Neurologic symptoms of children with *M. pneumoniae* in the California Encephalitis Project included altered consciousness (58%), seizures (40%), focal neurologic signs (37%), and hallucinations (18%).[106] Respiratory tract symptoms, reported in >80% of children with central nervous system involvement, precede neurologic symptoms by 7 to 10 days.[79,108] In patients with *M. pneumoniae* encephalitis or meningitis, CSF findings often are normal, but a mild, predominantly mononuclear pleocytosis (≤200 cells/mm^3) and protein elevation up to 70 to 80 mg/dL can occur; higher CSF white blood cell counts (>900 cells/mm^3) and protein concentrations (>170 mg/dL), although uncommon, have been described.[80–82,106]

Joint involvement in children appears to be less common than in adults. Monarthritis, polyarthritis, and migratory arthritis mimicking acute rheumatic fever have been described.[86,87,109–114] Limited information is available regarding synovial fluid analysis in patients with *M. pneumoniae*–associated arthritis; synovial pleocytosis has ranged from 1000 white bold cells/mm^3 in a child with hypogammaglobulinemia to approximately 50,000/mm^3 in an otherwise healthy child.[87,112] *M. pneumoniae*–associated glomerulonephritis has been described.[115–120] Glomerulonephritis appeared either concomitantly with other symptoms or 5 to 10 days later. Serum C3 complement level is decreased initially in some cases. Hematologic complications include the development of hemolytic anemia attributable to cross-reacting cold agglutinins,[76,105,121] thrombotic thrombocytopenic purpura,[122] and transient antiphospholipid antibody syndromes.[123,124]

Laboratory Findings and Diagnosis

Pathogen-Specific Identification

Culture

Many *Mycoplasma* species grow best in 5% to 10% carbon dioxide, but *M. pneumoniae* also grows well under aerobic conditions. The fermentation of simple carbohydrates, such as glucose, xylose, mannose, and maltose, provides a method for recognizing the growth of *Mycoplasma* in the laboratory. The complex nutritional requirements and slow growth on artificial media make identification by culture impractical for most laboratories and of limited value clinically. Because *M. pneumoniae* can persist in the respiratory tract for weeks to months after symptomatic or asymptomatic infection, recovery of the organism from the throat or sputum does not necessarily confirm causation of current disease.[25,44]

Cold Agglutinins

Cold-reacting antibodies against red blood cells can be detected in the serum of patients with primary atypical pneumonia.[39] Cold-agglutinating antibodies are immunoglobulin M (IgM) autoantibodies directed against the I antigen on human erythrocytes, which appear within 7 to 10 days of initial symptoms and drop sharply after 2 to 3 weeks.[29,45,125,126] In the laboratory, the highest dilution of serum causing hemagglutination or "clumping" of type O erythrocytes at 4°C is reported as the cold agglutinin titer. Titers >1 : 64 are present at the time of acute illness in approximately 75% of adults with *M. pneumoniae* pneumonia. The test is less well studied in children. Specificity of a titer <1 : 64 is low because various other respiratory tract pathogens provoke modest increases in cold agglutinins. For example, 18% of military recruits with adenoviral pneumonia had a cold agglutinin titer of ≥1 : 32.[127] Cold agglutinins should not be used for the diagnosis of *M. pneumoniae* infections if other methods are available. Bedside cold agglutinin testing lacks rigorous standards for performance and interpretation and is not recommended.

Serologic Examination

Methods to measure serum antibody include CF, indirect fluorescence, enzyme-immunoassays (EIA), and rapid EIA cards. Although CF testing has been the most widely available assay for detection of antibody to *M. pneumoniae,*[128] CF measures mainly IgM antibody, thus limiting its diagnostic value to initial rather than repeated infections.[96] An elevated CF antibody titer also should be interpreted with caution in patients with nonrespiratory disease because the antigens used in the CF test can cross-react with human tissue.[94–96]

CF tests have largely been replaced by less time-consuming and labor-intensive immunoglobulin assays, including EIA and immunofluorescence assay, and an indirect hemagglutination assay. These assays can be performed on a single serum specimen obtained during the acute infection, and they appear to be as sensitive as the CF test in children with pneumonia.[96,129–131] In adults, *M. pneumoniae* frequently represents a second infection, and IgM response does not occur reliably.[132,133]

EIA IgM assays are reported to be sensitive in children with pneumonia.[130] The ImmunoCard rapid IgM test (Meridian Bioscience, Cincinnati, Ohio) compared with other serologic tests (but not with PCR), using indirect fluorescence as the gold standard, had sensitivities ranging from 74% compared with EIA to 96% compared with CF; specificities ranged from 85% compared with the IgM-specific EIA to 98% compared with the IgM-specific indirect fluorescence.[134] Results were similar in a subsequent study of 145 children tested for *M. pneumoniae*.[135] False-positive IgM test results can occur, however, and predictive values of test results depend on pretest probability of *M. pneumoniae* infection. The specificity of IgM detection during a university and community outbreak of *M. pneumoniae* pneumonia was only 43% for children 10 to 18 years of age and 82% for those ≥19 years of age compared with a case-definition gold standard for diagnosis.[136] A combined IgG-IgM assay (Remel, Thermo Fisher Scientific, Lenexa, Kan) assessed during this outbreak had a higher specificity in children 10 to 18 years of age (74%) but a lower sensitivity (52%) compared with IgM detection (89%).[136] Other IgM assays appear to be as sensitive as PCR for detection of *M. pneumoniae* in CAP in children.[130]

IgG anti–*M. pneumoniae* can persist for months to years following infection. Testing for both IgM and IgG in paired specimens collected 2 to 3 weeks apart may provide the most accurate serologic diagnosis.[137] A fourfold or greater rise in antibody indicates a recent or current *M. pneumoniae* infection. Therefore accurate diagnosis often is made only retrospectively.

Molecular Methods

Molecular assays to detect *M. pneumoniae* are available.[130,131,138–143] PCR testing has detected *M. pneumoniae* in a variety of syndromes.

Use of primers against 2 different targets maximizes the ability to detect the organism; potential targets include the adenosine triphosphatase operon gene, P1 gene, conserved regions of 16S (small subunit) RNA, and the *tuf* gene.[144–148] Direct comparison of studies using PCR is difficult because specimens were obtained from different sites (e.g., nasal wash, nasopharyngeal swab, throat, sputum), and different primer sets and amplification techniques were used. Compared with seroconversion, sensitivity of some PCR-based tests has ranged from 79% for pharyngeal specimens to 90% for nasopharyngeal specimens; specificity was 98% when using these specimens.[148] Compared with culture, PCR has the advantage of an ability to detect *M. pneumoniae* genome in clinical settings when the organism may no longer be viable (e.g., in contaminated specimens or from tissue that has already been processed for histologic examination). Additionally, PCR test results can be positive earlier in the course of infection than serologic test results.

Testing of Extrapulmonary Specimens

Verification of extrapulmonary complications attributable to *M. pneumoniae* is challenging. Among children with encephalitis attributable to *M. pneumoniae* (defined by the presence of IgM anti–*M. pneumoniae* in acute or convalescent serum), intrathecal *M. pneumoniae* antibodies were detected rarely; IgM was found in 1 (3%) of 32 and IgG in 2 (12%) of 17 CSF samples.[106] The CSF PCR result was positive in 1 of 62 children with *M. pneumoniae* encephalitis; the patients with a positive CSF PCR result also had positive CSF IgM anti–*M. pneumoniae* result.[106] Smaller case series yielded similar findings.[149,150]

Additional Tests

Routine laboratory studies cannot distinguish among respiratory tract infections caused by *M. pneumoniae*, viruses, or other bacteria. The peripheral blood white blood cell count is normal or slightly elevated, with neutrophilia. Reported erythrocyte sedimentation rates range from 20 to >100 mm/hr, with higher rates reflecting more severe pulmonary disease.[40,151–153]

Chest radiography documents lower respiratory involvement, but few features differentiate *M. pneumoniae* infection from other conditions. Chest radiographs can show significant abnormality despite insignificant clinical symptoms. Bilateral interstitial infiltrates, as well as patchy, unilateral, segmental, or subsegmental consolidation, are described (Figs. 196.2 and 196.3).[154–156] Pleural effusions, reported in 20% of patients in 1 study when lateral decubitus views were obtained, usually are small and bilateral,[153–157] although large pleural effusions occur occasionally (Fig. 196.4).[51,53,54] Hilar lymphadenopathy, observed in 34% of children in 1 study, is seen more frequently in *M. pneumoniae* pneumonia than in pneumonia from most other common causes.[154]

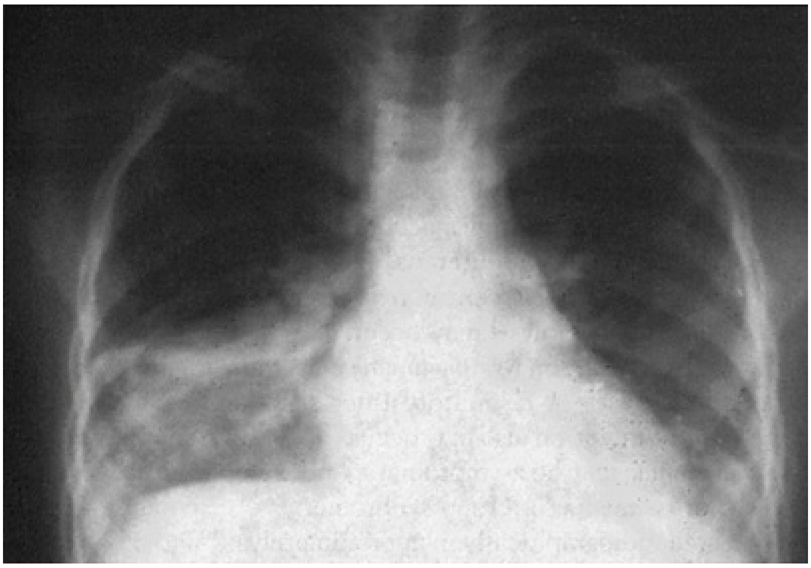

FIGURE 196.2 Chest radiograph of a 10-year-old girl with *Mycoplasma pneumoniae* pneumonia.

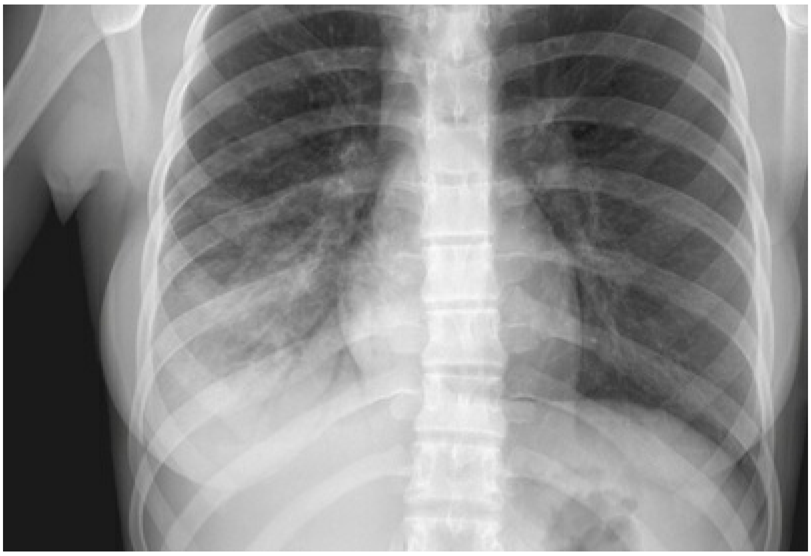

FIGURE 196.3 Chest radiograph in a 14-year-old boy with lobar pneumonia. Air bronchograms can be seen in the right lower lobe. *Mycoplasma pneumoniae* genome was detected in his nasopharynx and throat by polymerase chain reaction testing.

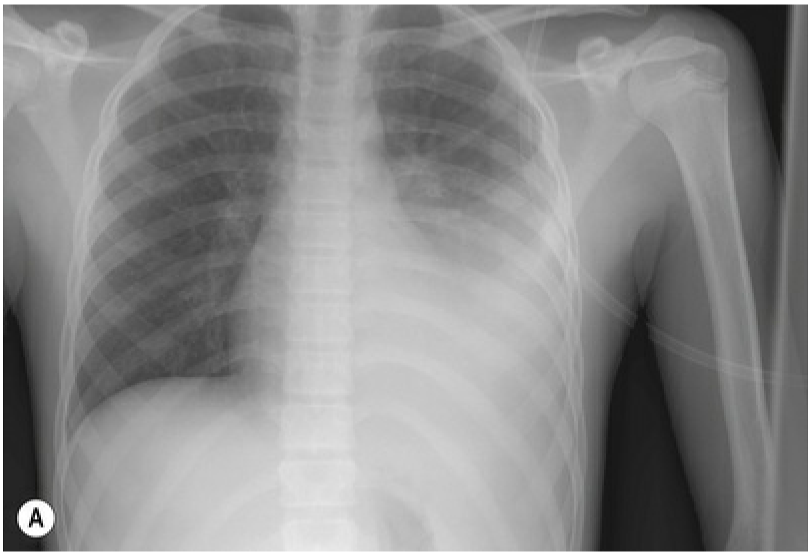

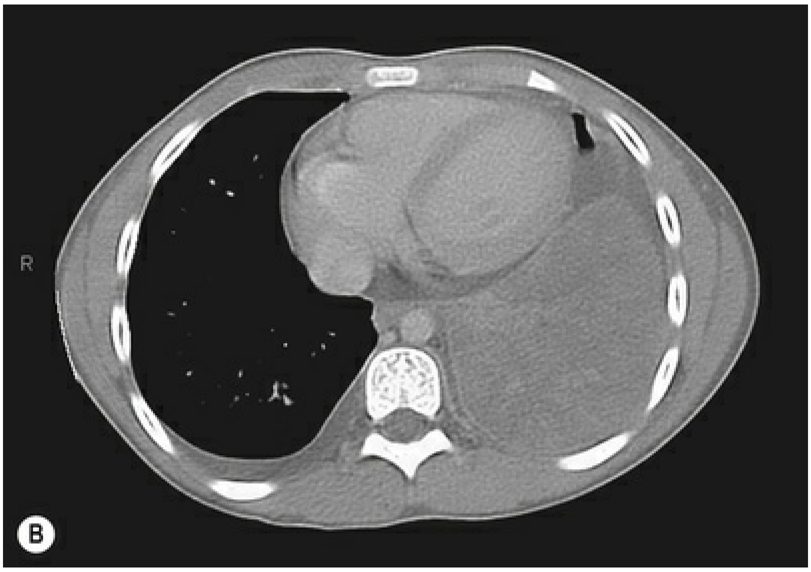

FIGURE 196.4 Radiography and computed tomography of the chest of a 13-year-old girl with *Mycoplasma pneumoniae* pneumonia complicated by parapneumonic effusion. (A) The radiograph demonstrates opacification of the left lung base with a moderate pleural effusion. (B) The computed tomography scan of the same patient also demonstrates a small right-sided pleural effusion and a trivial pericardial effusion.

Therapy

Antimicrobial Therapy

M. pneumoniae is inhibited in vitro by tetracyclines, macrolides, ketolides, and fluoroquinolones.[158–160] Fluoroquinolones appear bactericidal for *M. pneumoniae,* whereas macrolides, ketolides, and tetracyclines primarily are bacteriostatic[158]; the significance in patient outcomes is not known. The minimum inhibitory concentration (MIC) required to inhibit the growth of 90% of organisms (MIC_{90}) for levofloxacin ranges from 0.25 to 2 μg/mL[158,161–164]; the minimum bactericidal concentration is twofold higher. Moxifloxacin and gatifloxacin have somewhat greater activity in vitro compared with levofloxacin and ofloxacin. MIC_{90} values for all fluoroquinolones generally are severalfold higher than those of macrolides.[159,160] For azithromycin, clarithromycin, and telithromycin, the MIC_{90} values range from 0.001 to 0.015 μg/mL; minimum bactericidal concentration values often are eightfold to 16-fold higher.[158,159,161] Linezolid has minimal activity against *M. pneumoniae* (MIC_{90} >64 μg/mL).[163] Several other agents, including streptogramins, clindamycin, chloramphenicol, and aminoglycosides, demonstrate activity in vitro but are not effective clinically. β-Lactam and glycopeptide antibiotics have no activity against mycoplasmas.

The prevalence of clinically significant antibiotic resistance among *M. pneumoniae* isolates is not known; organisms from acute infection rarely are isolated in culture or tested in vitro for susceptibility to antibiotics. Macrolide resistance was reported in 12 (6.2%) of 195 clinical isolates in Japan.[165] The median MIC values were >32 μg/mL for azithromycin, clarithromycin, and telithromycin and 8 μg/mL for josamycin; however, the MIC values for minocycline and levofloxacin were similar between macrolide-susceptible and macrolide-resistant *M. pneumoniae* isolates.[165] Mutations in the peptidyl transferase loop of domain V of the 23S ribosomal RNA gene reduces the affinity of macrolides for ribosomes in both experimental models and clinical isolates.[166,167]

The benefit of antibiotic treatment of *M. pneumoniae* respiratory tract infections is uncertain. Azithromycin improves microbiologic, histologic, and immunologic markers of disease in experimental *M. pneumoniae* pneumonia in mice.[168] Studies comparing β-lactam and macrolide agents in the treatment of CAP in children included too few patients with *M. pneumoniae* to draw meaningful conclusions.[169] However, several lines of evidence suggest a possible therapeutic benefit. First, prophylactic oxytetracycline administered to family members of patients with *M. pneumoniae* infection prevented symptomatic infection (but not seroconversion).[170] Second, during epidemic *M. pneumoniae* infections in institutional settings, patients receiving azithromycin prophylaxis had significantly lower secondary attack rates than did patients not receiving prophylaxis.[34,171] Third, small retrospective studies showed that among children with atypical CAP (including *M. pneumoniae*), those treated with macrolides had a shorter duration of fever[172] and were less likely to have persistence or progression of signs and symptoms after 3 days of therapy.[173,174] In adults, Shames and colleagues[175] found a shorter duration of fever and hospitalization among erythromycin recipients compared with controls. No data suggest benefit of therapy for respiratory tract infections other than pneumonia.

Macrolide-class antibiotics also have been explored as potential treatments for *M. pneumoniae* because of their anti-inflammatory properties.[176–180] The importance of anti-inflammatory properties is supported by studies showing clinical cure in patients treated with macrolides despite persistence of *M. pneumoniae* organisms,[11,29,181,182] clinical improvement despite the administration of doses that provide tissue levels lower than the MIC of the organism,[183–185] and clinical cure in patients with macrolide-resistant *M. pneumoniae* infection.[166,186] The relative importance of the antimicrobial and anti-inflammatory effects of macrolide antibiotics in the treatment of *M. pneumoniae* is not known.

Therapy, if prescribed, may be more effective when started within 3 to 4 days of illness onset.[28,181,187] Therapeutic options for children include erythromycin (30–40 mg/kg/day divided into 4 doses for 7–14 days), clarithromycin (15 mg/kg/day divided into 2 doses for 7 to 14 days), or azithromycin (10 mg/kg once on the first day, followed by 5 mg/kg/day once daily for the next 4 days). Studies comparing erythromycin with clarithromycin[14,188] or azithromycin[189,190] for treatment of pneumonia did not identify a difference in frequency of therapeutic failure between the 2 groups; however, patients receiving erythromycin were twice as likely to have a drug-related adverse event, usually related to the gastrointestinal system. For adolescents, doxycycline (100 mg twice daily for 7–14 days), clarithromycin (500 mg twice daily for 7–14 days), azithromycin (500 mg on day 1, and 250 mg on days 2 to 5), or levofloxacin (500 mg once daily for 7–14 days) can be used. As few as 2% of patients with *M. pneumoniae* pneumonia require hospitalization, even in the presence of radiographic pneumonia.[28] Antibiotic therapy of *M. pneumoniae* infections has important limitations. The organism persists in many patients despite the antibiotic therapy; contagiousness thus extends through and after treatment. Because of the pathogen's persistence, relapsing infection should be considered in patients whose symptoms recur. Increasing resistance of *Streptococcus pneumoniae* to macrolides should prompt caution against using these agents alone for treatment of CAP.

No controlled studies of antibiotic or immunologic therapies for the nonrespiratory manifestations of *M. pneumoniae* infection have been conducted; no consistent benefit has been noted with antibiotic or corticosteroid therapy in individual patients. Because of the possibility of severe disseminated infection in immunocompromised patients, it is reasonable to administer an antibiotic with antimycoplasmal activity to patients with arthritis, central nervous system disease, hemolysis, or cardiac disease when *M. pneumoniae* infection is suspected.

Adjunctive Therapy

The effect of systemic or inhaled corticosteroids on infection-induced airway inflammation is poorly understood. Inhaled corticosteroids do not increase the infectious load of *M. pneumoniae*.[191] However, evidence supports efficacy. In experimentally infected mice, dexamethasone alone did not reduce *M. pneumoniae*–induced lung inflammation substantively compared with either placebo or clarithromycin monotherapy; however, combination therapy with clarithromycin and dexamethasone showed a significant reduction in lung inflammation compared with the other treatment regimens.[192] Anecdotal reports in children with *M. pneumoniae* pneumonia reveal temporal improvement of fever and radiologic abnormalities in association with corticosteroid therapy.[193]

Key Points

Diagnosis and Management of *Mycoplasma pneumoniae* Infection

Microbiology

- Pleomorphic bacteria without a cell wall, thus making it resistant to β-lactam antibiotics

Epidemiology

- Primarily a cause of upper and lower respiratory tract infection, although extrapulmonary complications occur

- Highest prevalence in school-aged children and adolescents, although younger children have less overt symptoms

- Attack rate among close contacts of 25% to 40%

- Clusters of infection in closed populations such as in institutionalized children and the military

Diagnosis

- Clinical findings suggestive
- Serologic testing (IgM anti–*Mycoplasma pneumoniae* detection in children or at least a fourfold rise in IgM or IgG) or PCR testing of nasopharyngeal washing or throat swab specimen

Treatment

- Role of antibiotic treatment for pneumonia uncertain
- Generally susceptible in vitro to macrolides, fluoroquinolones, and tetracyclines

IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction.

Other *Mycoplasma* Species

Samir S. Shah

Many Mollicutes colonize the mucosal surfaces of humans (Table 197.1). Of these organisms, only *Mycoplasma genitalium, Mycoplasma hominis, Mycoplasma pneumoniae* (see Chapter 196), and *Ureaplasma urealyticum* (see Chapter 198) are known to be pathogenic for healthy humans. Other *Mycoplasma* spp. have been isolated in pure culture from nonmucosal sites in immunocompromised people, a finding indicating that commensal species can cause disease in some circumstances. In addition, animal *Mycoplasma* spp. occasionally cause local wound infection in humans.[1]

TABLE 197.1

Sites of Colonization or Infection of Mollicutes in Humans

Species	Primary Colonization Site
Acholeplasma laidlawii	Oropharynx
Acholeplasma oculi	?
Mycoplasma amphoriforme	Oropharynx
Mycoplasma buccale	Oropharynx
Mycoplasma faucium	Oropharynx
Mycoplasma fermentans	Lower genital tract, respiratory tract
Mycoplasma genitalium	Oropharynx, genital tract
Mycoplasma hominis	Lower genital tract, oropharynx
Mycoplasma lipophilum	Oropharynx
Mycoplasma orale	Oropharynx
Mycoplasma penetrans	Genital tract
Mycoplasma pirum	?
Mycoplasma pneumoniae	Oropharynx, trachea, bronchial tree, lung, pleural fluid

Mycoplasma primatum	Genital tract
Mycoplasma salivarium	Oropharynx
Mycoplasma spermatophilum	Cervix, sperm
Ureaplasma parvum	Genital tract
Ureaplasma urealyticum	Genital tract

Adapted from Tully G. Current status of the mollicute flora of humans. Clin Infect Dis 1993;17(Suppl 1):S2.

Mycoplasma hominis

M. hominis commonly colonizes the lower genitourinary tract of healthy men and women. In general, women are more likely to be colonized than men, and the likelihood of colonization increases with the number of sexual partners.[2–4] *M. hominis* is found in <5% of asymptomatic men and in as many as 20% of men attending sexually transmitted disease clinics.[5] The rate of colonization in asymptomatic women ranges from 10% to 30%[6,7]; the rate of isolation may be higher in women with bacterial vaginosis,[8,9] urethritis, or cervicitis.[10] Adolescent girls and boys are colonized infrequently, with reported rates of approximately 5% and 2%, respectively.[11] *M. hominis* seldom colonizes the upper respiratory tract; it has been recovered from the oral or respiratory tracts of 1% to 3% of healthy adults and in a greater proportion of those adults who engage in oral-genital sexual practices.[12] *M. hominis* also was identified in 4.7% of 319 children undergoing bronchoscopy, with the prevalence decreasing with increasing age; the clinical relevance of this finding is uncertain.[13]

The respiratory and genitourinary tracts of neonates also can be colonized (incidence, 2%–7%), particularly after birth complicated by prolonged rupture of amniotic membranes or amnionitis.[7]

Isolation of the organism from normally sterile sites and documentation of immunologic response to infection have implicated *M. hominis* as a cause of the conditions listed in Table 197.2. Numerous case reports implicate *M. hominis* as a cause of amnionitis, postpartum fever,[14–21] and other postpartum infections.[22] However, the clinical importance of neonatal *M. hominis* infection is less clear.[23] Neonatal central nervous system infections attributed to *M. hominis* include ventriculitis, meningitis, meningoencephalitis, and subdural empyema.[24–35] *M. hominis* was isolated from the cerebrospinal fluid (CSF) of 5 (5%) of 100 preterm infants 1 to 6 days of age; the 1 infant with CSF pleocytosis had 71 white blood cells/mm^3 and a mononuclear cell predominance.[28] Valencia and colleagues[26] isolated *M. hominis* from 9 (13%) of 69 neonates undergoing lumbar puncture; the CSF white blood cell count ranged from 0 to 28 white blood cells/mm^3. *M. hominis* also was isolated from the CSF in 9 (2.8%) of 318 infants evaluated by lumbar puncture in the peripartum period at 4 community hospitals; the 1 infant who died had concomitant *Haemophilus influenzae* sepsis.[27] Neonates who did not receive specific therapy for *M. hominis* in these studies did not appear to have any apparent clinical consequence of infection.[26–28] In contrast, Wolthers and associates[33] reported a term infant with early onset meningoencephalitis attributed to *M. hominis* that was identified by both culture and polymerase chain reaction (PCR) testing of the CSF; this infant had improvement in CSF abnormalities that coincided with the administration of ciprofloxacin.

TABLE 197.2

Infection Associated With *Mycoplasma hominis*[a]

Age Group	Type of Infection
Neonate	Septicemia
	Meningitis
	Ventriculitis
	Brain abscess or subdural empyema
	Pneumonia
	Pericarditis
	Wound infection
	Submandibular adenitis
	Subcutaneous abscess
Infants and children	Septicemia
	Ventriculitis
	Pleural effusion
Adolescents and adults	Amnionitis
	Postpartum fever
	Pyelonephritis or perinephric abscess
	Septicemia
	Wound infection
	Intravascular infection
	Arthritis
	Ventriculitis
	Upper respiratory tract infection (parapharyngeal abscess)
	Pneumonia or pleural infection

[a] Nongenitourinary infections almost always occur in patients with immune compromise because of severe burns, collagen-vascular disease, severe trauma, malignant disease, organ transplantation, or congenital immunodeficiency,

particularly hypogammaglobulinemia.

Recovery of *M. hominis* from the respiratory or urinary tract of neonates generally has not been associated with clinical infection.[36,37] However, neonates with *M. hominis* isolated from sterile sites appear to have worse clinical outcomes. In a study of 351 preterm infants (23–32 weeks of gestational age), *M. hominis* was isolated from umbilical cord blood cultures alone (n = 21; 6.0%) or in combination with *Ureaplasma urealyticum* (n = 18; 5.1%); earlier gestational age correlated with a higher rate of positive umbilical cord blood culture results. Furthermore, infants with positive umbilical cord blood culture results were more likely to have systemic inflammatory response syndrome compared with infants with negative cord blood culture results.[38]

Numerous anecdotal reports have recorded *M. hominis* infection occurring outside the genitourinary system in other populations, including immunocompromised patients[39–49] and patients undergoing intracranial oeprations.[50,51] In a series of 36 adults with extragenital *M. hominis* infection, patients most commonly had abdominal wound infections following genitourinary tract operations.[52]

M. hominis infection should be suspected when specimens from localized purulent infection, especially following genitourinary tract exposure (e.g., neonate) or manipulation, fails to yield a pathogen by conventional laboratory methods. Isolation and identification of *M. hominis* require inoculation and initial incubation in beef heart infusion broth containing horse serum and yeast extract, available commercially as pleuropneumonia-like organism (PPLO) broth. Arginine, which is metabolized by *M. hominis,* is added to the broth, along with phenol red. Metabolism of arginine increases the pH so that growth can be detected by a change in the color of the broth, usually within 24 to 48 hours. Subculture onto solid agar and incubation in 95% nitrogen and 5% carbon dioxide yield, within 7 days, colonies of 200 to 300 μm that develop the characteristic “fried egg” appearance. *M. hominis* (but not *M. pneumoniae* or *U. urealyticum*) also grows on conventional blood agar and in most broth media used for blood culture. Laboratory personnel should be alerted to look for pinpoint, translucent colonies that develop within 2 to 3 days on blood agar that should be subcultured as described. Recognition of *M. hominis* growth in blood culture broth depends on blind subculture, even if results of Gram stain of broth are negative. Growth causes little turbidity in broth, but radiometric assays show a positive growth index within 5 to 7 days.[21] Automated, continuous-monitoring blood culture systems do not permit reliable recovery of *M. hominis*.[53] Multiplex PCR[54] and PCR-based microtiter plate hybridization assays[55] also have been described; their accuracy and usefulness in the clinical setting remain to be determined.

Generally, *M. hominis* is susceptible to tetracyclines, fluoroquinolones, and clindamycin.[56–59] The minimum inhibitory concentration required to inhibit the growth of 90% of organisms (MIC_{90}) values are lower for levofloxacin (0.19–0.5 μg/mL), gatifloxacin (0.063 μg/mL), and moxifloxacin (0.063 μg/mL) than for ciprofloxacin (0.5–1 μg/mL).[56,58,60] Chloramphenicol, rifampin, and linezolid (MIC_{90}, 8.0 μg/mL) demonstrate modest in vitro activity.[61] Up to 20% of *M. hominis* clinical isolates can be resistant to tetracycline and doxycycline, but antibiotic susceptibility patterns vary by country.[56,62–64] Fluoroquinolone resistance occurs occasionally.[39,65] Unlike the other pathogenic mycoplasmas, *M. hominis* is almost always resistant to macrolides, azalides, and ketolides, including erythromycin, azithromycin, clarithromycin, and telithromycin.[61,64,66,67] The benefit of immune globulin intravenous therapy in patients with hypogammaglobulinemia and *M. hominis* infection is not known.

Mycoplasma Genitalium

M. genitalium was first isolated in 1980 from urethral specimens of 2 men with symptoms of nongonococcal urethritis.[68] Clarifying the subsequent role of *M. genitalium* in human disease has been hampered by the organism's slow growth, fastidious cultivation requirements, and serologic cross-reactivity of surface antigens with *M. pneumoniae*.[69] The 38% to 63% rate of detection of *M. genitalium* in sexual partners of index cases compared with 6% in a control population suggests that the infection is sexually transmitted.[70,71] Numerous studies using PCR confirm the association of *M. genitalium* with nongonococcal urethritis in men.[71–75] Fewer studies of *M. genitalium* have been carried out in women. The prevalence of *M. genitalium* of 6% among asymptomatic women attending a sexual health clinic was comparable with that of *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.[76] *M. genitalium* has been detected using PCR techniques in women with acute and chronic urethritis and pelvic inflammatory disease.[77–79] Women with pelvic inflammatory disease attributed to *M. genitalium* have a milder spectrum of symptoms compared with women with gonococcal pelvic inflammatory disease.[80]

Repeat examination of presumed *M. pneumoniae* isolates from respiratory specimens obtained in the 1970s and from synovial fluid of a patient with hypogammaglobulinemia and polyarthritis showed that some isolates actually were mixed *M. pneumoniae* and *M. genitalium* infections.[81,82] Although *M. genitalium* is associated with nongonococcal urethritis in men, its association with other human diseases of the genitourinary or respiratory tract remains uncertain. The twofold higher prevalence of *M. genitalium* among HIV-infected patients also warrants investigation of potential causal associations.[83]

The organism is typically detected by PCR of urethral or cervical swabs or urine specimens.[84–86] *M. genitalium* is susceptible to tetracyclines, fluoroquinolones, and macrolides.[87,88] MICs vary widely; MICs <0.01 µg/mL for macrolides, azalides, fluoroquinolones, and tetracyclines generally are considered susceptible, and MICs ≥2 µg/mL generally are considered resistant.[89] Mutations that occur in region V of the 23S ribosomal RNA gene prevent macrolide binding.[90] Such mutations are present in more than one third of isolates in studies including at least 100 specimens[91–93]; the prevalence of resistance is higher in posttreatment specimens obtained from patients whose therapy failed.[89]

Azithromycin may be preferable to doxycycline for treatment of *M. genitalium* infection because doxycycline does not consistently eradicate *M. genitalium* from the genitourinary tract.[94–96] Among 398 men with urethritis who were enrolled in a randomized clinical trial, 13% of azithromycin-treated men remained culture positive compared with 55% of doxycycline-treated men.[96] In 1 study, colonization persisted in 20 (67%) of 30 patients treated with doxycycline but in 0 of 36 patients treated with azithromycin.[95]

Observational studies suggest that a single 1-g dose of azithromycin, versus doses given over 5 to 7 days,[70,97–100] results in a similar rate of eradication. Clinical and microbiologic treatment failure following moxifloxacin, previously rare, is reported in up to 30% of patients in contemporary studies; however, most of these patients received moxifloxacin after having treatment failure with another antimicrobial agent.[89,91,101]

Other *Mycoplasma* Infections

M. fermentans, M. penetrans, and other "nonpathogenic" species have been isolated from patients, including children with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome.[102–104] In most instances, infection appeared to be asymptomatic, but serious and fatal disease has been reported.[105,106] Investigators have speculated that *Mycoplasma* spp. can enhance the pathogenicity of HIV by a variety of mechanisms, but evidence is insufficient to prove that *Mycoplasma* spp. are more than opportunistic pathogens.

Human infections with zoonotic *Mycoplasma* spp. have been reported predominantly in immunocompromised patients[107] and in patients with trauma and wound contamination.[1] Because these infections appear to be uncommon, routine attempts to recover *Mycoplasma* spp. are not warranted. However, in unusual circumstances, such as an immunocompromised patient with negative results of routine bacterial cultures or a patient with an infected wound after a seal bite, culture for *Mycoplasma* spp. should be considered. "Seal finger," an infection known to occur in seal hunters and wildlife workers, can result from a seal bite or from skinning or handling seals.[1,108,109] Several different species of marine *Mycoplasma* found in the mouths and respiratory tracts of seals are the presumed cause. Tetracyclines are considered first-line therapy for seal finger.

Certain illnesses including chronic fatigue syndrome, Gulf War syndrome, and fibromyalgia have been associated with positive results of PCR testing of blood for 1 or more *Mycoplasma* spp.[110,111] These associations should be considered speculative at best. Additional studies in subjects with Gulf War syndrome have shown no such association.[112] Further, a placebo-controlled trial of doxycycline in 491 subjects with Gulf War veterans' illnesses that were characterized by pain, fatigue, and cognitive symptoms, and detectable *Mycoplasma* DNA in blood did not demonstrate benefit in functional status 1 year after randomization.[113] Although such reports may warrant further well-designed studies, PCR testing for *Mycoplasma* spp. should not be considered part of the clinical investigation for such patients.

Ureaplasma urealyticum

Samir S. Shah

Microbiology

Members of the family Mycoplasmataceae are small pleomorphic bacteria that characteristically lack a cell wall. Shapes range from filamentous to spherical, with diameters up to 0.8 µm. The genus *Ureaplasma* is biochemically unique in that all members possess urease and therefore hydrolyze urea to produce adenosine triphosphate. Ammonia also is produced, and it increases the pH and limits growth in culture. *Ureaplasma urealyticum* was first described in 1950 by Shepard, who noted minute colonies growing amid larger *Mycoplasma* colonies in specimens taken from the urethra and urine of men with nongonococcal urethritis.[1] These bacteria were initially called “T-strain” *Mycoplasma* because of their tiny colony size. Urease production led to the name *Ureaplasma urealyticum.*

U. urealyticum, a human pathogen, has historically been divided into 14 serotypes, which are divided into 2 distinct biovars on the basis of biochemical and genetic features. Genetic study suggests that the 2 biovars represent 2 separate species; *U. urealyticum* biovar 1 (*Ureaplasma parvum*) includes serovars 1, 3, 6, and 14, and *U. urealyticum* biovar 2 is further divided into 3 subtypes. Subtype 1 includes serovars 2, 5, 8, and 9. Subtype 2 includes serovars 4, 10, 12, and 13, and subtype 3 includes serovars 7 and 11.[2] The entire genome of *U. urealyticum* has been sequenced.[3] It is the smallest sequenced prokaryotic genome, except for *Mycoplasma genitalium,* and it consists of only 75 DNA kilobase pairs. The function of at least 50% of the 652 identified genes remains unknown. The description of the genome facilitates improved understanding of the mechanism of disease caused by these elusive organisms.

Epidemiology

Ureaplasma spp. colonize the urogenital tract of healthy adults and adolescents. *Ureaplasma* spp. can be found on the mucosal surfaces of the cervix or vagina of 40% to 80% of healthy women. Reported rates of asymptomatic urethral carriage of *U. urealyticum* among men typically range from 20% to 50%; however, most studies have assessed only sexually active men in the context of medical visits for urologic evaluation or sexually transmitted infection.[4–7] One report found that urethral carriage was detected in only 8 (7%) of 114 asymptomatic male volunteers recruited from hospital staff and from primary care practices.[8] Although colonization occurs less frequently among adolescents and young children, its presence is related to both sex and sexual activity. Foy and colleagues[9] isolated *Ureaplasma* spp. from the urine of 1% of adolescent boys and 15% of adolescent girls; girls who reported dating members of the opposite sex were more likely to be colonized. The organism was not recovered from any of 101 children <13 years of age.[9] Approximately 50% of colonized mothers transmit the organisms to their infants.[10–12] Peripartum colonization occurs most often in infants born >1 hour following rupture of membranes[10] and in infants weighing <1000 g.[11] Sites of colonization in infants, in order of decreasing frequency, include the vagina, nasopharynx and throat, rectum, and conjunctiva.[10–12] Colonization persisted at 3 months of age in 37%, 68%, and 33% of infants with initial vaginal, throat, or conjunctival colonization, respectively, in 1 study.[12] Other studies have noted disappearance of peripartum colonization by 2 years of age.[13]

Clinical Manifestations

A causal relationship between *U. urealyticum* and various clinical syndromes has been difficult to confirm, given the relatively high frequency of asymptomatic carriage and the difficulty in collecting samples from normally sterile sites. Many published studies failed to adjust for potentially important confounding variables or were underpowered to detect significant associations. Nevertheless, *U. urealyticum* has been shown to cause urethritis. In pregnant women, *Ureaplasma* is an implicated cause of chorioamnionitis, spontaneous abortion, stillbirth, preterm delivery, and postpartum endometritis. *U. urealyticum* has been associated with longterm sequelae such as chronic lung disease in preterm infants. Invasive infections have been reported, predominantly in neonates and immunocompromised people. The reported association with infertility in adults is controversial.

Urethritis

Nongonococcal urethritis in men appears to be associated with *U. urealyticum* biovar 2 but not biovar 1 (*U. parvum*).[14,15] Clinical symptoms do not distinguish *Ureaplasma* spp. infection from other causes of nongonococcal urethritis. Among men, biovar 2 has been isolated 2 to 3 times more frequently from men with nongonococcal urethritis than from asymptomatic men.[5,6,16] Among men with *U. urealyticum* detected in urine by 16S ribosomal RNA (rRNA) polymerase chain reaction (PCR), quantity of detection was significantly higher in men with urethritis compared with men without symptoms.[14,17] A bacterial load of $\geq 10^4$ *U. urealyticum* 16S rRNA gene copies/mL in a first-void urine specimen (initial 20–30 mL of urine after not having urinated for at least 2 hours) has been proposed to distinguish urethritis from asymptomatic colonization, although validation in larger populations is required.[17] Coinfection with *U. urealyticum* also conferred 3.6-fold greater odds of postgonococcal urethritis (urethritis that persists after successful eradication of laboratory-confirmed gonococcal infection).[18] Although young boys usually are not colonized, recurrent urethritis was attributed to *U. urealyticum* in a 7-year-old boy.[19]

Although the role of *U. parvum* in urethritis is unclear, current data suggest that this organism rarely causes urethritis. In a meta-analysis, *U. parvum* was detected more often from urethral specimens of 1223 control subjects (17.7%) than from 1507 subjects with nongonococcal urethritis (10.2%; $P < 0.001$).[15] Additionally, the quantity of *U. parvum* detected usually is low and does not differ significantly between men with and men without urethritis.[14] However, higher loads of *U. parvum* were associated with higher first-void urine white blood cell counts in a male study.[20] Although *U. parvum* could contribute to urethritis, routine testing or treatment is not warranted.

Intrauterine and Neonatal Infection

Ureaplasma spp. have been isolated from the placenta and fetus after spontaneous abortion in individual case reports.[21,22] *U. urealyticum* was isolated from the placenta more often in cases of spontaneous abortion, stillbirth, or neonatal death (31%) than in control liveborn infants (9%) in 1 study.[23] Several studies supported the association between *U. urealyticum* and chorioamnionitis. In a case-control study, Abele-Horn and associates[24] demonstrated a dose-response relationship between the density of vaginal colonization with *U. urealyticum* and clinical chorioamnionitis risk; chorioamnionitis was more likely in women with moderate (odds ratio [OR], 2.5; 95% confidence interval [CI], 1.0–5.9) or heavy (OR, 7.2; 95% CI, 3.3–15.5) vaginal colonization than in uncolonized women. Histologic evidence of chorioamnionitis is present more frequently when *U. urealyticum* is isolated from either amniotic fluid[25] or newborn infants.[26] Colonization was detected in 18 (38%) of 48 infants whose placentas exhibited histologic evidence of chorioamnionitis and in 22 (19%) of 116 infants with normal maternal placentas ($P = 0.02$).[26] Although smaller studies have not shown differences in frequency of *U. urealyticum* isolation from amniotic fluid of women with or without chorioamnionitis,[27] a nonrandomized study of women colonized with *U. urealyticum* revealed significantly fewer midtrimester losses in the 35 women who received oral erythromycin (11%) compared with the 9 women who were not treated (44%; $P = 0.04$).[28]

Isolation of *U. urealyticum* from the amniotic fluid (but not from the lower vaginal tract) appears to be associated with preterm delivery. *U. urealyticum* has been detected in the amniotic fluid of approximately 9% of women in preterm labor and is associated with a higher risk of preterm delivery and adverse neonatal outcomes in this setting.[29–31] Cytokines elaborated in the amniotic fluid in response to the presence of microorganisms, including *U. urealyticum*, trigger prostaglandin synthesis, which can lead to uterine contractions and cervical dilation.[32] However, in a prospective study of 4934 women from 5 medical centers who were evaluated for vaginal colonization with *U. urealyticum* between 23 and 26 weeks of gestation and who were followed to delivery, preterm delivery was not associated with *U. urealyticum* vaginal colonization after adjustment for medical and sociodemographic factors (OR, 1.0; 95% CI, 0.8–1.2).[33]

U. urealyticum appears to have a causal role in chronic lung disease of prematurity, perhaps by stimulating the production of proinflammatory mediators, including neutrophils, tumor necrosis factor-α, and interleukin-8.[34,35] Animal models supported this assertion. Rodent macrophage cell lines released nitric oxide in the presence of *U. urealyticum.*[36] Premature baboons artificially colonized with *U. urealyticum* developed classic hyaline membrane disease and necrotizing bronchiolitis.[37,38] In a meta-analysis, pulmonary colonization with *Ureaplasma* spp. was associated with chronic lung disease when measured at 28 days of life (31 studies; OR, 3.0; 95% CI, 2.4–3.8) and at 36 weeks of postmenstrual age (17 studies; OR, 2.2; 95% CI, 1.4–3.5).[39] Gestational age did not influence this relationship, a finding suggesting a causal role rather than a confounding factor of gestational age. Limitations of the meta-analysis,[39] and of other studies,[40–48] include differences in methods to detect *Ureaplasma* spp. and inconsistent reporting of the use of surfactant and corticosteroids. *U. parvum* was detected in tracheal secretions more than twice as often as *U. urealyticum*; no difference was observed between infants harboring *U. parvum* versus *U. urealyticum* in development of chronic lung disease.[44] However, detection of both species simultaneously occurred more often in infants with than without chronic lung disease (17 vs. 7 infants, respectively) (OR, 3.0; 95% CI, 1.2–7.7; P = 0.01).

U. urealyticum can cause invasive disease in neonates. Individual cases of congenital pneumonia have been associated with *Ureaplasma* spp.[49] One study demonstrated concomitant *U. urealyticum* bacteremia in 26% of preterm neonates with *U. urealyticum* isolated from endotracheal aspirates.[50] The clinical manifestations in infants with *U. urealyticum* isolated from cerebrospinal fluid (CSF) specimens range from subclinical infections with complete recovery to suppurative infections associated with longterm sequelae. In 1 study, *U. urealyticum* was isolated from the CSF of 8 of 100 infants undergoing lumbar puncture either for suspected meningitis or for treatment of hydrocephalus[51]; some infants had *U. urealyticum* isolated from multiple CSF specimens. The CSF white blood cell counts ranged from 0 to 5240 cells/mm^3.[51] Case reports include a 3-week-old infant with brain abscess attributed to mixed infection with *U. urealyticum* and *Mycoplasma hominis*,[52] a 7-day old infant with meningitis complicated by subdural collections with *U. urealyticum* isolated from CSF and improvement following azithromycin and ciprofloxacin therapy,[53] an untreated neonate with *Ureaplasma* isolated from CSF who remained well,[54] and a premature infant with intraventricular hemorrhage and isolation of *U. urealyticum* from CSF without pleocytosis.[55] The prognosis and neurodevelopmental outcomes of infants with *Ureaplasma* spp. infections of the CSF have not been studied.

Other Infections

Some reports suggested an etiologic role for *U. urealyticum* in several focal infections, including pneumonia,[56–61] arthritis,[62–64] meningitis,[65] renal abscesses,[66,67] and postoperative mediastinitis.[68] Focal infections usually have been reported in immunocompromised patients. *U. urealyticum* has been recovered in cultures of respiratory tract secretions (usually in combination with other respiratory pathogens) obtained from both immunocompetent and immunocompromised infants with lower respiratory tract infections,[56,58–61] as well as from bronchoalveolar lavage fluid in 3 children with cancer during a period of acute respiratory deterioration.[57] *U. urealyticum* has been recovered from blood or joint fluid in patients with agammaglobulinemia and pyogenic arthritis,[62,63] and it has been detected by PCR in joint fluid in a patient with reactive polyarthritis[64] and in a patient with recurrent arthritis following treatment with rituximab and adalimumab for juvenile idiopathic arthritis.[69] Meningitis[65] and renal abscesses[66,67] have been described in adults following renal transplantation.

Laboratory Findings and Diagnosis

Ureaplasma spp. are fastidious. Body fluid specimens or material collected on calcium alginate or Dacron-tipped swabs should be inoculated at the bedside into a special transport or growth medium, such as Shepard 10B broth, and then inoculated onto solid media as soon as possible. Freezing decreases viability, but if the sample must be held, freezing at −70°C is recommended. Inoculation onto A8 or a commercial solid medium that contains urea allows rapid growth, generally within 2 to 5 days. An indicator dye added to the medium to detect hydrolysis of urea permits early identification of *Ureaplasma* spp.

In culture, the organisms are ovoid. On solid media, the organism shares the upside-down "fried egg" appearance typical of Mycoplasmataceae. Organisms vary in size but are approximately 350 nm in diameter, too small to be seen with a light microscope. Growth can be detected in broth or on agar when a specialized culture medium is used. Distinct small colony morphologic features (on appropriate media) and passage in selective broth permit culture identification but not serovar classification.

PCR is a faster and more practical approach to detection. Gene targets include the urease,[70] 16S rRNA,[71] and multiple-banded antigen[72,73] genes. Amplification of the multiple-banded antigen gene allows biovar and, possibly, serovar identification.[2,72–74] Multiplex PCR for simultaneous detection of *U. urealyticum*, *Trichomonas vaginalis*, and *Mycoplasma hominis* has been developed.[75] The sensitivity of multiplex PCR for detection of *U. urealyticum* was 96% compared with culture or one of several PCR assays.[75] PCR for *Ureaplasma* spp. performed on gastric fluid on the day of birth has high specificity but poor sensitivity (27%) compared with PCR of amniotic fluid within the 7 days before delivery.[76]

Treatment

No well-established breakpoints exist for determining antimicrobial susceptibility of *U. urealyticum*. However, most *Ureaplasma* spp.

have minimal inhibitory concentrations (MICs) for erythromycin in the range of 0.125 to 4 μg/mL, a finding that suggests susceptibility. Resistant strains (MIC, e.g., ≥8 μg/mL) are reported.[77] The MICs of azithromycin (range, 0.125–2 μg/mL) and clarithromycin (range, 0.06–2 μg/mL) are slightly lower compared with the MIC of erythromycin.[78–81] MICs of doxycycline range from 0.016 to 1 μg/mL.[77,78] Acquisition of the *tet*M determinant mediates tetracycline resistance.[82,83] Generally, >90% of clinical isolates are susceptible in vitro to levofloxacin, moxifloxacin, ofloxacin, and chloramphenicol in most studies, whereas <50% are susceptible to ciprofloxacin or clindamycin.[78,79,81,84–86] Quinupristin-dalfopristin and telithromycin also appear to have adequate activity against *U. urealyticum* (MIC_{90} [MIC required to inhibit the growth of 90% of organisms] <0.25 μg/mL).[81] Although some *Ureaplasma* spp. isolates appear susceptible to aminoglycosides in vitro, these agents do not have clinical efficacy. *Ureaplasma* spp. lack peptidoglycan and are not susceptible to β-lactam agents or vancomycin.

Urethritis can be treated with azithromycin, doxycycline, or newer-generation fluoroquinolones. In a randomized, double-blind multicenter trial, microbiologic cure rates of *U. urealyticum* urethritis among men were 45% for those receiving azithromycin (1 g, single dose) and 47% for those receiving doxycycline (100 mg, twice daily for 7 days).[87] A subsequent double-blind clinical trial of men with *U. urealyticum* nongonococcal urethritis found higher microbiologic cure rates: 75% for azithromycin recipients (n = 65; 1 g) and 70% for doxycycline recipients (n = 77; 100 mg, twice daily for 7 days).[88] In a treatment follow-up study, persistent detection of *U. urealyticum* was not associated with persistent urethritis.[89] Women with >3 weeks of symptoms had higher rates of clinical cure and eradication after the administration of azithromycin at a dose of 500 mg daily for 6 days than after a single 1-g dose.[90] Macrolides may be less effective than doxycycline in the acidic environment of the female genital tract.[81,91]

Making specific recommendations for treating invasive *Ureaplasma* spp. infections in neonates is difficult because the spectrum of disease in this population has not been elucidated fully. Furthermore, drug options are limited, clinical studies of antibiotic efficacy are not available, conditions under which treatment should be offered are controversial, and the optimal duration of therapy, when prescribed, is not known. Because of the proven ability of *U. urealyticum* to induce inflammation in the lung and CSF, detection from a normally sterile body site in the absence of another organism would seem to justify specific therapy. Erythromycin (25–40 mg/kg/day in 4 divided doses) is the drug of choice for treating infections outside the central nervous system. In older children, azithromycin is associated with less gastrointestinal discomfort and better adherence. Therapy generally is continued for 5 (azithromycin) or 10 days (erythromycin or clarithromycin). If therapy of central nervous system infection is considered, an agent with better penetration of the blood-brain barrier than erythromycin should be selected. In such cases, it may be prudent to document recovery of the organism from multiple CSF samples before initiating therapy. In a report of a neonate with a brain abscess attributed to *U. urealyticum* and *M. hominis* treated with a combination of doxycycline 4 mg/kg/day and erythromycin for 6 weeks, a doxycycline concentration of 1.0 µg/mL in ventricular fluid was documented.[52]

Although *U. urealyticum* colonization is associated with development of chronic lung disease, treatment of colonized neonates does not improve their outcomes. In a meta-analysis of 6 studies involving 469 preterm infants, no significant reduction was noted in chronic lung disease (relative risk, 0.64; 95% CI, 0.31–1.31) or in the composite outcome of chronic lung disease or death (relative risk, 0.41; 95% CI, 0.05–3.13) when macrolides (azithromycin in 3 studies, erythromycin in 2, and clarithromycin in 1) were used in *Ureaplasma*-positive infants.[92] In the largest study, which contributed one third of the patients to the meta-analysis and did not observe a reduction in chronic lung disease, azithromycin was given at a dose of 10 mg/kg/day for 7 days followed by 5 mg/kg/day for up to 6 weeks.[93] Higher doses of azithromycin (i.e., 20 mg/kg/day) have better *Ureaplasma* clearance and greater anti-inflammatory action.[84,94] Whether these higher doses lead to better outcomes in preterm infants with *Ureaplasma* pulmonary colonization is unknown. Evidence is also insufficient to determine benefit of treatment of women with *Ureaplasma* vaginal colonization to prevent preterm birth[95,96]; such treatment is therefore not recommended.

Diseases of Possible Infectious or Unknown Etiology

OUTLINE

199 Kawasaki Disease
200 Chronic Fatigue Syndrome

199

Kawasaki Disease

Anne H. Rowley

Kawasaki disease (KD) is the most common cause of acquired heart disease in children in the developed world.[1] The epidemiology and clinical features of the illness point to an infectious etiology, but the cause remains unknown. KD is a unique vasculitis that occurs in previously healthy young children and can result in serious long-term coronary artery disease or death.[2] Approximately 20% of children with KD who are not treated with intravenously administered immune globulin (IGIV) develop coronary artery abnormalities.[3]

KD is named after Tomisaku Kawasaki, who first recognized the clinical features of the illness in Japanese children in the 1960s.[4] By 1970, the coronary artery sequelae became apparent when some children who were recovering from KD suddenly died from coronary artery aneurysms with thrombosis and myocardial infarction. Before Kawasaki's description of the clinical features, the disease was recognized only at autopsy and was called *infantile periarteritis nodosa* by pathologists.[5]

The illness is recognized worldwide and affects children of all ethnic groups. More than 290,000 cases were diagnosed in Japan by 2012.[6] The total number of cases diagnosed to date in the United States and other countries is uncertain. Symptomatic or fatal ischemic coronary artery disease in adolescents and young adults with angiographic or pathologic characteristics highly suggestive of KD sequelae has been recognized increasingly.[7,8]

Etiology and Epidemiology

KD is an illness of infants and young children. Approximately 80% of patients are younger than 5 years of age.[6,9] Because children older than 8 years of age account for a small percentage of KD patients, the diagnosis may be delayed for this age group.[10] Males are more commonly affected than females (3 : 2). Epidemics of KD have been observed in Japan and other countries, with a geographic wave-like spread of cases as the epidemic progresses.[11,12] The illness recurs in about 3% of Japanese children; the recurrence rate in the United States likely is lower.[6]

The annual incidence of KD among Japanese children is about 260 cases per 100,000 children younger than 5 years of age.[6] Approximately 1% of Japanese children develop KD by age 5 years. Asian children who live in non-Asian countries continue to experience high rates of KD. The attack rate of KD among white children is 10-fold lower than among Asians, and African Americans appear to have an intermediate incidence. Attack rates can increase substantially during epidemics in all ethnic groups; a calculated annual attack rate during an outbreak of KD in the Rochester, NY, area increased from about 10 to 180 cases per 100,000 children younger than 5 years of age.[13]

Epidemiologic features strongly suggest a ubiquitous microbe as the causative agent. The rarity of KD in infants younger than 3 months is compatible with protection from passive maternal antibodies, and the virtual lack of KD in adults suggests widespread immunity. The winter-to-spring predominance of cases in temperate climates, epidemics of illness, and the wave-like spread of illness during outbreaks are all consistent with an infectious cause. Little evidence of person-to-person spread of KD exists. However, because most ubiquitous microbes result in asymptomatic infection in most of the population, person-to-person spread may be difficult to document without knowledge of the causative agent.

In a study of Japanese children with KD, the risk of developing a second case in a family within 1 year after onset of the first case was significantly higher than the risk of KD for the general population of age-matched children. Moreover, more than one half of second cases in families developed within 10 days of the first case.[14] These findings suggest common exposure to an infectious agent in genetically predisposed individuals. Children with KD usually are healthy before the onset of illness and are not more likely than unaffected children to develop subsequent autoimmune disease or recurrent infections.

A variety of known infectious agents have been proposed to be causative, but none has been associated consistently, leading some investigators to propose multiple causes for KD. However, research studies support the hypothesis that KD results from infection with a single, currently unidentified respiratory viral agent.[15–17]

Pathology

In acute KD, inflammatory cells, including T lymphocytes, particularly CD8$^+$ cells; plasma cells, many of the IgA isotype; eosinophils; and macrophages infiltrate medium-sized muscular arteries, particularly the coronary arteries,[18–20] and selected nonvascular tissues.[21] This remarkable IgA immune response suggests a mucosal portal of entry of the etiologic agent.

The stimulus for inflammatory cell infiltration in tissues in acute KD is unclear. Possibilities include direct infection of tissues by the etiologic agent or an immune response to self, perhaps triggered by a mechanism of molecular mimicry. The former seems more likely because the systemic inflammatory process resolves spontaneously within a few months of onset. The result is necrotizing arteritis of the coronary artery walls, which can be catastrophic. The walls can balloon and form aneurysms. Sluggish blood flow in these abnormal vessels encourages coronary thrombosis and resultant myocardial infarction. If the wall is severely weakened, it can rupture, causing sudden death. Marked myocarditis can result in arrhythmia. Pericarditis commonly leads to pericardial effusion, and as inflammation of the sac progresses, more fluid is produced.

Marked innate immune activation in acute KD manifests by upregulation of cytokines in the peripheral blood.[22,23] The robust oligoclonal, antigen-driven immune responses by T lymphocytes[24] and immunoglobulin M (IgM) and IgA B lymphocytes[25,26] attest to strong adaptive immune responses. Other immunologic findings include decreased CD8$^+$ T lymphocytes in the peripheral blood[27] and elevation of all serum immunoglobulins in the subacute phase of illness.[28] Polymorphisms in several immune system genes are associated with KD susceptibility and the risk of coronary artery abnormalities, but even in combination, these genes do not explain the increased incidence among Asian children.[29]

Although the systemic inflammatory process gradually subsides within 2 to 3 months after onset in most cases, subacute or chronic arteritis can persist for months to years in the most severely affected patients, and pathologic changes of severely affected arteries can persist over time.[30] Luminal myofibroblastic proliferation can occur in arteries damaged by KD and lead to progressive stenosis of the vessel, with the potential for myocardial ischemia and infarction.[30]

Clinical Manifestations

The clinical course of KD can be divided into three phases. The acute phase usually lasts 7 to 14 days and manifests as fever, conjunctival injection without exudate; oral and pharyngeal redness, strawberry tongue and red, cracked, bleeding lips without oral ulcerations; swelling and erythema of the hands and feet; polymorphous rash; and cervical lymphadenopathy. These findings form the basis for the classic diagnostic criteria (Box 199.1), which requires fever plus four of five of the clinical features of illness.

Box 199.1

Diagnostic Criteria for Kawasaki Disease

Fever persisting for at least 5 days[a]

Four of the following clinical findings:

- Bilateral conjunctival injection
- Erythema of the oropharynx, with fissuring of the lips and strawberry tongue
- Erythema and swelling of the hands and feet, with subsequent periungual desquamation
- Erythematous rash

- Cervical lymph node enlargement to >1.5 cm in diameter

Illness not explained by other known disease process

---

[a]The diagnosis of Kawasaki disease may be made by experienced physicians before the fifth day of fever.

Young children are very irritable and often refuse to walk or bear weight during the acute phase. Marked tachycardia resulting from myocarditis is common. Although cervical lymphadenopathy usually is the least common of the five clinical features of KD, it can be the predominant symptom. Enlarged cervical lymph nodes in KD usually are tender to palpation, occasionally erythematous, and typically unilateral, with a diameter of greater than 2 cm. These patients often are treated for bacterial adenitis without success and referred with that diagnosis; they can also have retropharyngeal nonsuppurative phlegmon.[31,32]

The rash in KD can be maculopapular, scarlatiniform, or erythema multiforme–like (Fig. 199.1). Vesicles and bullae do not occur. Perineal accentuation of the rash occurs in two thirds of patients.[33] Perineal involvement commonly is misdiagnosed as candidal diaper dermatitis; it also occurs in toilet-trained children. Associated features of the illness are described in Table 199.1.[3,34–49]

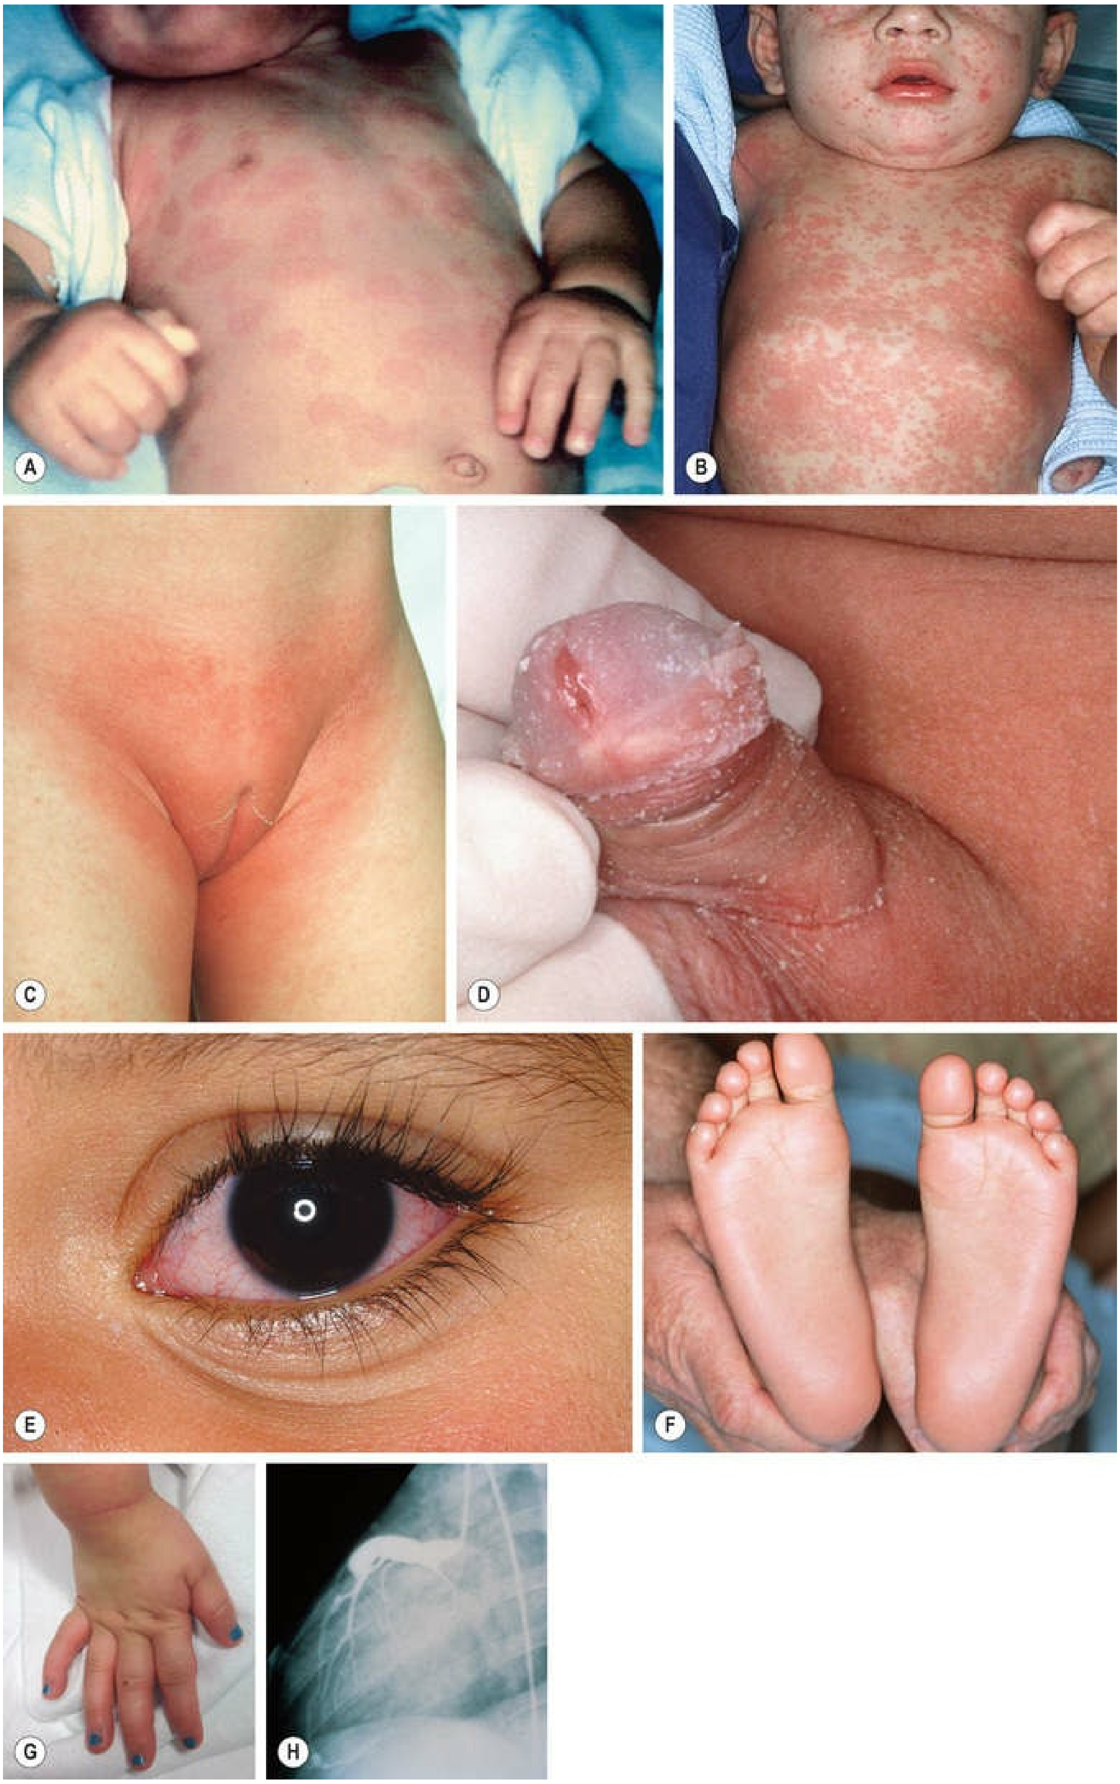

FIGURE 199.1 Clinical manifestations of Kawasaki

disease. (A) Erythema multiforme-like rash and swollen hands. (B) Morbilliform rash. (C) Erythematous, desquamating perineal rash. (D) Desquamating periurethral rash. (E) Bulbar conjunctival erythema. (F) Erythema and edema of feet (i.e., loss of plantar creases). (G) Glove-like distribution of erythema of the hand. (H) Saccular aneurysm of the right coronary artery on day 8 of fever in 6-month-old boy. (A, Courtesy of A.H. Rowley; B–F, courtesy of J.H. Brien ©; G and H, courtesy of S.S. Long.)

TABLE 199.1

Features of Kawasaki Disease

Feature	Incidence	References
CARDIOVASCULAR		
Coronary artery aneurysms	25% untreated; 4% IGIV treated	3, 34
Other systemic artery aneurysms	2%	35
Myocarditis	>50%	36
Pericarditis	25%	36
Valvular disease	1%	36
NEUROLOGIC		
Extreme irritability	>90% in infants; less common in older children	37
Aseptic meningitis	40%	38
Facial palsy	<1%	39
GASTROINTESTINAL		
Hepatitis	50%	40
Jaundice	<10%	40
Pancreatitis	Unknown; probably common but usually mild	41, 42
Gallbladder hydrops	10%	37
Diarrhea	25–50%	37
GENITOURINARY		
Urethritis	50–90%	43
Hydrocele	25–50%	44
MUSCULOSKELETAL		
Arthralgia and arthritis	33% untreated; 8% IGIV treated	45
RESPIRATORY		
Preceding respiratory illness	50–90%	13
Pneumonitis, radiologic but not clinical evidence	15%	46
OTHER FINDINGS		
Anterior uveitis	25–50%	47
Erythema and induration at BCG inoculation site	50%	48
Peripheral gangrene	<1%	49

BCG, bacille Calmette-Guérin; IGIV, immune globulin intravenous.

Rarely, patients with KD can be in shock at presentation, often resulting in a delayed diagnosis. They can have thrombocytopenia, are more likely to have refractory KD, and have an increased risk of coronary artery abnormalities.[50–52]

In the subacute phase, fever, rash, and lymphadenopathy resolve, but conjunctival injection and irritability often persist. Periungual desquamation of the fingers and toes, arthritis, and thrombocytosis are characteristic of the subacute phase, which occurs from about day 10 to day 25 after the onset of fever. Beau lines (i.e., transverse grooves in the nails) can be observed in the late subacute stage. Temporary hair loss can occur.

The convalescent phase begins when all clinical signs of illness have resolved and continues until the erythrocyte sedimentation rate (ESR) becomes normal, usually 6 to 8 weeks after the onset of illness. Prolonged fever and recurrence of fever after apparent resolution are associated with an increased risk of coronary artery sequelae.[53] Other risk factors include age younger than 1 year, duration of fever for more than 16 days, recurrence of fever after an afebrile period of at least 48 hours, anemia, thrombocytopenia, and hypoalbuminemia.[53–55]

Incomplete KD is a challenge. Incomplete KD (preferred to the term *atypical KD*) refers to the lack of full diagnostic criteria for KD, not atypical or extra clinical findings. Worldwide, young children (often infants) with KD can have fever and fewer than four clinical features of the illness. Unfortunately, infants are at higher risk than older children for coronary artery abnormalities.[56]

Patients with incomplete KD appear to have laboratory features similar to those of patients with classic presentations. If coronary artery dilation is detected on echocardiography (i.e., Z score for left anterior descending or right coronary artery ≥2.5), the patient should be treated for KD. An algorithm published by the American Heart Association incorporates clinical features, laboratory data, and echocardiographic findings to assist the clinician in decision making regarding diagnosis and treatment for suspected incomplete KD.[54]

Laboratory Findings and Diagnosis

Certain laboratory findings are characteristic, although none is diagnostic (Table 199.2).[34,37,38,40,43,45,54–56] Thrombocytosis occurs at a mean time of 2 weeks after onset and is therefore not useful in making a diagnosis in the acute stage, during which therapy should be instituted. IGIV therapy does not appear to prevent thrombocytosis.[54] The ESR usually is elevated markedly, but the ESR can be artifactually low in the acute phase in a subset of KD patients with consumption coagulopathy; the C-reactive protein level in these children is very high.[57] A persistently elevated ESR for 4 to 6 weeks after fever onset is characteristic of KD in IGIV-treated and untreated patients. A transient increase in the ESR can occur in IGIV-treated patients due to the effect of immune globulins on red blood cell sedimentation. After administering IGIV, the C-reactive protein level is a more useful assay for monitoring inflammation in a persistently febrile child.

TABLE 199.2

Characteristic Laboratory Findings in Kawasaki Disease

Finding	Incidence	Comment	References
Leukocytosis	All	≥15,000/mm^3 or left shift	3, 34
Anemia[a]	50–90%	Normochromic, normocytic	53, 54, 55
Hypoalbuminemia[a]	10–50%		54
Elevated acute phase reactants	>90%	ESR usually >40 mm/hr C-reactive protein[a] ≥3 mg/dL	3, 34
Sterile pyuria	50–90%	Can be intermittent	43
Proteinuria	<10%		37
Serum transaminase elevation[a]	37%	Mean serum ALT of 100 U/L	40
Serum bilirubin elevation	13%		40
Arthritis	33% untreated	Cell count >25,000/mm^3, predominantly neutrophils, in 80% of patients	45
	8% IGIV treated		
CSF pleocytosis	40%	Median cell count 20 cells/mm^3 with 90% neutrophils, 10% mononuclear cells; glucose and protein levels usually normal	38
Thrombocytosis	>90%	In subacute phase, 500,000 to 2,000,000/mm^3	34, 54

[a] Severity correlates with risk of coronary artery disease.

ALT, alanine aminotransferase; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; IGIV, immune globulin intravenous.

Echocardiographic studies should be obtained at diagnosis, 1 to 2 weeks later, and 6 to 8 weeks after fever onset. Additional studies may be unnecessary if all three studies are normal. If a patient demonstrates abnormalities on any of the three echocardiograms, additional studies are necessary.

KD can be difficult to differentiate from other febrile illnesses of childhood (Box 199.2). Measles and group A streptococcal or staphylococcal infections most closely resemble KD. In uncomplicated measles, the white blood cell count and ESR usually are low; a measles IgM antibody test can confirm the diagnosis. It is sometimes difficult to differentiate acute infection due to group A *Streptococcus* from KD in a group A streptococcal carrier. Treatment with penicillin for 24 to 48 hours followed by clinical reassessment usually clarifies the diagnosis because patients with KD do not respond to antibiotic therapy. The finding of a concurrent respiratory viral infection should not exclude a diagnosis of KD because the incidence peaks during the winter months, when many respiratory viruses are circulating. Unilateral cervical lymphadenitis in KD is not suppurative.[32]

Box 199.2

Conditions That Share Clinical Features With Kawasaki Disease

Measles

Group A streptococcal infection (including scarlet fever)

Toxic shock syndrome

Stevens-Johnson syndrome

Drug reactions

Juvenile idiopathic arthritis

Adenovirus infection

Leptospirosis

Rocky Mountain spotted fever

Although some of the clinical features in KD are found in a variety of infectious and inflammatory diseases of childhood, certain clinical features strongly suggest KD as the diagnosis.[58]

Conjunctival injection in KD is primarily bulbar and usually without exudate. Lip redness and swelling can be severe enough to cause cracking and bleeding, and strawberry tongue is characteristic. Oral ulcerations and exudative pharyngitis are not features. Firm induration of the hands and feet with or without palmar and plantar erythema is distinctive, often is associated with refusal to walk or hold objects, and is rarely seen in other childhood febrile illnesses. Perineal accentuation of the rash without accentuation at other skin folds is common in KD but not in other disorders. Vesicles, bullae, petechiae, or purpura make KD unlikely.

Treatment

Current therapy for KD during the acute phase of illness is aimed at reducing clinical symptoms, reducing inflammation in the myocardium and in the coronary artery wall to prevent coronary aneurysm formation, and preventing thrombosis by inhibiting platelet aggregation. Discovery of the cause of KD will allow more specific treatment.

IGIV was first used in Japan to successfully treat KD.[59] The mechanism of action of IGIV in KD is unknown. Subsequent multicenter studies in the United States confirmed the efficacy of IGIV with aspirin for KD. IGIV given within the first 10 days of illness hastens resolution of fever and a decrease in levels of acute phase reactants. The prevalence of coronary artery abnormalities is about 20% among aspirin-treated patients but about 5% among those treated with IGIV and aspirin.[3,35] All KD patients should be treated as early as possible after diagnosis; it is not necessary to wait until the fifth day of fever in patients who clearly have the disease. Data regarding treatment after the 10th day of illness are lacking; however, patients who remain febrile or continue to have markedly elevated inflammatory markers are likely to benefit from IGIV even after the 10th day. For patients who receive IGIV but nonetheless develop coronary aneurysms, there is a higher rate of normalization of coronary artery diameter than for untreated patients.

The recommended dosage of IGIV is 2 g/kg, given as a single infusion over 10 to 12 hours.[35] Patients also should receive anti-inflammatory doses of aspirin (80 to 100 mg/kg/day), given orally in divided doses every 6 hours; high doses are given because of poor aspirin absorption and increased clearance in acute KD. The aspirin dose is reduced to 3 to 5 mg/kg/day for antithrombotic effects on the 14th day of illness or when the patient has been afebrile for 3 days. Low-dose aspirin therapy is discontinued 6 to 8 weeks after onset of disease if coronary arteries are normal by echocardiography and if the ESR is normal. Aspirin therapy can be interrupted if the patient develops an illness suspected to be varicella or influenza to reduce the risk of Reye syndrome. For patients at particularly high risk for myocardial infarction, the use of an alternative antiplatelet agent should be considered.

Most patients have a dramatic response to IGIV, but about 10% to 15% continue to be febrile 36 hours or longer after completing the IGIV infusion. A second 2-g/kg dose of IGIV appears to be effective in most of these patients,[60–62] although a controlled study of retreatment has not been performed. In patients who do not respond to two doses of IGIV, pulsed methylprednisolone therapy at 30 mg/kg/day for 3 days or a single dose of infliximab (i.e., monoclonal antibody to tumor necrosis factor-α) at 5 mg/kg has been associated with apparent clinical response.[63–66]

Patients who fail to respond to multiple therapies have been treated with calcineurin inhibitors such as cyclosporine to reduce T-lymphocyte activation.[67] The efficacy of various treatments for patients unresponsive to IGIV is uncertain because controlled trials have not been performed and the clinical features of acute KD are self-limited. Rarely, IGIV therapy can result in complications such as aseptic meningitis or hemolytic anemia.

Although corticosteroid therapy did not appear useful in the primary treatment of KD before the advent of IGIV therapy,[64,68,69] it was studied in combination with IGIV for primary therapy of selected high-risk patients. A trial of single-dose intravenous methylprednisolone with IGIV and aspirin for primary therapy of nonselected US children with acute KD showed no benefit in coronary outcomes or fever days.[70]

In contrast, a study of Japanese children considered to be at high risk because of a Kobayashi score of 5 or more showed a significant benefit for the addition of prednisolone to IGIV for primary therapy.[71] Prednisolone was given intravenously as 2 mg/kg/day for 5 days and then orally until the C-reactive protein level normalized, followed by tapering over the next 15 days.[71] Unfortunately, KD risk scoring systems have not proved sufficiently sensitive to allow identification of high-risk, multiethnic North American children, limiting the applicability of this regimen to non-Japanese populations.[72] A trial of IGIV plus adjunctive infliximab for primary therapy in nonselected US children did not show a clear benefit.[73]

For patients who develop persistent coronary artery abnormalities, long-term, low-dose aspirin therapy at 3 to 5 mg/kg/day is indicated. This therapy often is recommended for patients with coronary artery aneurysmal dilation that has resolved as determined by echocardiography. Studies show that regression of aneurysms occurs by thrombosis or luminal myofibroblastic proliferation; these arteries are not normal.[30,74–77] KD patients with large aneurysms may benefit from warfarin or low-dose heparin therapy. Occasionally, acute thrombolytic therapy is needed in patients with thrombosis of large aneurysms; the decisions should be made in consultation with a pediatric cardiologist.

Long-term management of coronary artery sequelae of KD has been summarized by the American Heart Association Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease.[54] Rarely, patients with KD require intervention such as transluminal coronary angioplasty, transluminal coronary rotational ablation, coronary atherectomy or stent implantation,[78] coronary artery bypass surgery,[79] or heart transplantation.[80] Long-term prognosis depends on the severity of coronary artery disease. Patients with giant or many large aneurysms are most likely to require multiple catheter interventions or bypass procedures, and long-term survival is likely to be shortened. Data on increased risk of atherosclerosis among KD patients during adulthood are lacking.

The routine administration of live, attenuated viral vaccines, such as measles, mumps, rubella, and varicella vaccines, should be delayed for 11 months after IGIV treatment for KD. Schedules for administration of other routine childhood vaccinations should not be interrupted. Inactivated injectable influenza vaccine is recommended annually for all children and is crucial for those receiving long-term aspirin therapy.

Special Considerations

After establishment of normative data for coronary artery diameter based on body surface area, it was reported that 30% of KD children have coronary artery dilation as established by echocardiogram at diagnosis in the first 10 days of illness.[81,82] The peak time to observe coronary artery aneurysms is in the second to third week after the onset of illness. The development of aneurysms after the sixth week of illness is rare. At 1 year after onset of KD, echocardiographic resolution of coronary artery luminal dilation is seen for 50% of patients. However, intracoronary ultrasonography demonstrates that these vessels have persistent abnormalities, such as luminal narrowing.[76,77]

Patients with giant coronary artery aneurysms, which historically were defined by an internal diameter of at least 8 mm but are more accurately defined by a coronary artery diameter Z score of ≥10, are at greatest risk for coronary thrombosis, stenosis, and myocardial infarction.[2,83] Patients with giant coronary artery aneurysms can sometimes develop aneurysms of the iliac, axillary, femoral, and renal arteries.

Prevention of KD is not possible until the cause of the disorder is identified.

Key Points

Diagnosis and Management of Kawasaki Disease

Epidemiology

- Most patients are 6 months to 5 years of age, but KD can occur in younger and older children.

- Highest attack rate is among Asian children; 1% of Japanese children develop KD by age 5.

- Epidemics have a geographic wave-like spread.

- KD probably is caused by a ubiquitous infectious agent that results in disease in a small subset of genetically predisposed children.

Clinical Features

- Multisystem inflammatory disorder

- Classic KD: fever for ≥5 days with four of the five other findings (see Box 199.1)

- Incomplete KD: prolonged fever with fewer than four of the five clinical findings, with compatible laboratory and echocardiographic findings and no other explanation for illness

- Most serious complication is coronary artery dilation with aneurysm formation.

Diagnosis

- Diagnosis of classic KD is based on clinical criteria.

- Diagnosis of incomplete KD is based on clinical, laboratory, and echocardiographic findings.

Treatment

- IGIV (2 g/kg) is given over 10–12 hr with aspirin (80–100 mg/kg/day divided every 6 hr).

- Aspirin is reduced to 3–5 mg/kg/day as a single daily dose when the patient has been afebrile for at least 3 days and is continued until acute phase reactants and echocardiogram are normal at 6–8 weeks after onset of fever or indefinitely if coronary artery abnormalities develop or persist.

Chronic Fatigue Syndrome

Gary S. Marshall, Bryan D. Carter

Chronic fatigue syndrome (CFS) manifests as profound, debilitating fatigue associated with subjective complaints and resulting in functional impairment. Symptoms begin abruptly and persist for years. In the 1980s, case clusters and associations with Epstein-Barr virus (EBV) infection heightened awareness of the condition and led to the use of terms such as *chronic mononucleosis* and *chronic EBV*.[1–5] These terms imply a causal relationship with EBV infection that has not been established. The term *myalgic encephalomyelitis* implies an unproven pathogenesis, and the term *chronic fatigue syndrome* may be stigmatizing. In 2015, the Institute of Medicine (IOM) recommended abandoning previous terminology in favor of *systemic exertion intolerance disease*.[6]

Skepticism about CFS as a distinct diagnosis has yielded to acceptance.[7] Clinicians usually have little difficulty suspecting the syndrome but may have great difficulty diagnosing by exclusion, sorting comorbidities, and guiding patients to recovery.

Case Definition

A case definition that was formulated by the Centers for Disease Control and Prevention (CDC) in 1994,[8] modified in 2003,[9] and validated in 2005[10] has been widely used in research. Alternative definitions—notably the 2003 Canadian Clinical Case Definition[11] and the 2011 International Consensus Criteria[12]—have been offered. In 2015, the IOM proposed new diagnostic criteria (Box 200.1) focused on core symptoms of the disease: impaired functioning, postexertional malaise, and unrefreshing sleep.[6]

Box 200.1

Proposed Diagnostic Criteria for Chronic Fatigue Syndrome, 2015[a]

Each of the following symptoms

- Substantial reduction or impairment in ability to engage in preillness levels of occupational, educational, social, or personal activities that persists for >6 months and is accompanied by fatigue[b]
- Postexertional malaise[c,d]
- Unrefreshing sleep[d,e]

And at least one of the following manifestations

- Cognitive impairment[d]
- Orthostatic intolerance[f]

---

[a] The 2015 Institute of Medicine report[6] used the term *myalgic encephalomyelitis/chronic fatigue syndrome* but recommended renaming the syndrome *systemic exertion intolerance disease*.

[b] Fatigue is often profound and of new or definite onset (not lifelong); it is not the result of ongoing excessive exertion and not substantially alleviated by rest.

[c] Prolonged exacerbation of baseline symptoms occurs after physical, cognitive, or orthostatic stress (may be delayed relative to the trigger).

[d] The diagnosis should be questioned if these symptoms are not present at least one half of the time with moderate, substantial, or severe intensity.

[e] Polysomnography is not required for the diagnosis but may be indicated to screen for treatable sleep disorders; diagnosis of a primary sleep disorder does not rule out a diagnosis of chronic fatigue syndrome.

[f] Prolonged orthostatic testing (i.e., standing test or upright tilt test) is not required for diagnosis but may be indicated to diagnose conditions such as postural tachycardia syndrome, neurally mediated hypotension, or orthostatic hypotension

that would be amenable to therapy.

Modified from Institute of Medicine. Beyond myalgic encephalomyelitis/chronic fatigue syndrome: redefining an illness. Washington, DC, National Academies Press, 2015. http://www.nap.edu/openbook.php?record_id=19012.

Few adults with fatigue met the 1994 CDC case definition,[13–18] and diagnosing CFS was complicated by overlap with other unexplained syndromes and comorbid conditions.[8,9,11,19–23] Moreover, CFS in adults is a heterogeneous disorder, and distinct subgroups may exist.[10,24–27] Historical definitions of CFS were difficult to apply to children[28–32]; guidelines for pediatric diagnosis include those from the Royal College of Paediatrics and Child Health (2004),[33] the International Association for CFS/ME (2006),[34] the National Institute for Health and Care Excellence (2007),[35] and the International Consensus Panel (2011).[12] The 2015 IOM definition, which requires symptoms to be present for more than 6 months, is meant to apply to children; however, many pediatric experts do not wait that long to begin investigation.[11,28–30,35] Phenotypes in children are heterogeneous, and only a subset of children have adult-like CFS.[36]

Epidemiology

Separate studies in Wichita, Kansas, and Chicago, Illinois, estimated the prevalence of CFS to be about 200 to 400 cases per 100,000 adults.[37,38] In another study, Georgia residents were screened for *unwellness,* and standardized instruments were used to identify CFS cases[39]; the prevalence of CFS was 2.5% and did not vary by geographic region. CFS was less prevalent among men in metropolitan areas (0.4%) than in rural areas (2.9%), and the prevalence among women in metropolitan areas was 11 times higher than among men. There was no relationship with race, level of education, or income. Similar prevalence rates have been found in England[40] and Australia.[41]

Whereas upper middle class individuals appear to be overrepresented in clinics,[2–5,16,42–44] population-based studies show high rates in minority and lower socioeconomic groups.[37,38,45] To some extent, this can be explained by social strain, lack of social support, physical inactivity, anxiety, and depression.[46] Clusters of

CFS have been reported,[5,47,48] but there is no evidence of person-to-person transmission.

Fatigue is extremely common among adolescents[49–51] and is a common reason for referral to pediatric infectious diseases specialists.[52,53] Few children, however, meet historical case definitions of CFS,[49] and CFS-like illness appears to be rare in children younger than 12 years of age.[54,55] The Wichita study failed to identify any adolescents who met the 1994 CDC case definition, but CFS-like illness was seen at a rate of 338 cases per 100,000 adolescents.[56] The prevalence of CFS was estimated at 111 cases per 100,000 Dutch adolescents[57]; 45% of CFS patients reported a rate of school absence of more than 50% for the previous 6 months, highlighting CFS as a cause of extreme dysfunction and disability among teenagers. Some population-based studies show that girls are more commonly affected than boys,[31,54,55] and girls are overrepresented in clinic populations.[52,53,58,59–62]

Pathophysiology

Infection

Although CFS often follows a distinct infectious mononucleosis– or flu-like illness, there is no evidence that any single infectious agent causes CFS. Many agents have been investigated (Box 200.2)[1–5,16,47,63–140]; invariably, initial excitement that the cause of CFS was found has yielded to skepticism and ultimately to disappointment.

Box 200.2

Infectious Agents That Have Been Studied as a Cause of Chronic Fatigue Syndrome[a]

Herpesviruses

Epstein-Barr virus[1–5,16,47,63–71]

Cytomegalovirus[5,16,66,67,69,71,76,77]

Herpes simplex virus[66,69]

Human herpesvirus 6[16,44,47,52,66,67,69,71–75,78,79–81]

Human herpesvirus 7[67,69,72–75]

Human herpesvirus 8[69,78]

Varicella-zoster virus[8,69]

Other Viruses

Adenovirus[71]

Arboviruses[8]

BK virus[69]

Borna disease virus[86,87,88]

Enteroviruses[66,71,89–102]

GB virus-C[109]

Hepatitis B virus (or vaccine)[66,110]

Hepatitis C virus[66,112]

Inoue–Melnick virus[124]

JC virus[69]

Measles virus[66]

Parvovirus[66,69,71,82–85]

Respiratory viruses[66]

Retroviruses (including human endogenous retroviruses)[47,66,75,103–108]

Rubella[66]

Stealth virus[111]

Xenotropic murine leukemia virus-related virus[113–123]

Bacteria, Fungi, and Parasites

Bartonella henselae[66]

Borrelia burgdorferi[71,126,127]

Candida[66,133–136]

Chlamydia[66,137]

Ehrlichia[66]

Gram-negative enteric bacteria[139,140]

Gram-positive enteric bacteria[125]

Mycoplasma[128–132]

Rickettsia[66]

Toxoplasma[16]

16S rDNA sequences[138]

---

[a] None of these agents is demonstrably causal in the pathogenesis of chronic fatigue syndrome, although infection with some (e.g., Epstein-Barr virus) can trigger the disease.

A good example was the purported association between CFS and infection with xenotropic murine leukemia virus–related virus (XMRV) suggested in papers (subsequently retracted) from different laboratories in 2009[113] and 2010.[114] XMRV is a retrovirus originally thought to be associated with human prostate cancer, but it was later determined to have arisen from the recombination of two murine proviruses during passage of prostate cancer cells through mice.[115] Many laboratories were unable to replicate the initial findings.[116–121] A multicenter, blinded study of 147 geographically diverse CFS patients and 146 healthy controls found no evidence of XMRV DNA or DNA of the related polytropic murine leukemia virus in any subject.[122]

In another study, blinded specimens from patients previously reported to have XMRV were sent along with controls to nine different laboratories; only two laboratories reported positive results, replicate samples were discordant, and no differences were found between patients and controls.[123] Findings in the earlier studies likely resulted from contamination.

The complex relationship between infectious agents and CFS is illustrated by EBV. EBV-induced infectious mononucleosis often results in fatigue for more than 6 months.[141,142] All EBV infections are chronic in that the virus establishes lifelong latency. Initial serologic findings suggested that CFS patients had continued active EBV infection,[1–4] but subsequent studies showed inconsistencies in serologic results, nonspecifically elevated antibodies to several viruses, and failure of virus detection to identify cases.[5,16,47,64–70] Patients with true chronic active EBV infection have end-organ involvement and low levels of antibody to EBV nuclear antigen,[143] findings that are not seen in CFS.

A distinct, disabling, persistent fatigue syndrome can follow a variety of acute infections.[144] In the case of EBV, postinfectious fatigue syndrome (PIFS) is not associated with increased viral load or lytic replication.[70] Whether associated with EBV or other infectious agents, PIFS is not associated with increased cytokine production, a surprising finding given the overlap between the physiologic effects of cytokines and symptoms of CFS.[145,146] Some CFS patients may have PIFS triggered by EBV, but the condition is not specifically driven by the virus. Poor physical functioning early in the course of infectious mononucleosis predicts prolonged fatigue afterward, suggesting that the acute illness leads to deconditioning, which leads to perpetuation of symptoms.[147] Likewise, the severity of illness is linked to the risk of developing CFS.[148]

Immunology

Patients with CFS do not manifest immunodeficiency in the classic sense, with recurrent or opportunistic infections. However, symptoms of the illness suggest viral infection, and reactivation of latent viruses suggests relaxation of immunologic surveillance. Allergy symptoms are common and autoantibodies have been reported.[149,150]

There are many controlled studies of the immunology of CFS.[a] The most consistent finding is decreased NK cell function despite normal numbers of NK cells.[b] B-lymphocyte number, B-lymphocyte function, and immunoglobulin levels usually are normal.[151–153,155–161,163] Inconsistent results have been seen in T-lymphocyte number and function,[16,151–165] mononuclear cell activation,[c] and circulating cytokines, cytokine production, soluble receptors, and other inflammatory or antiviral markers.[d] Any proposed connection between laboratory abnormalities and clinical manifestations is confounded by interactions among psychological well-being, the neuroendocrine system, and immune function.

Cardiovascular Physiology

Some studies suggest an etiologic role for orthostatic intolerance in CFS,[193–196] whereas others provide less convincing evidence for altered autonomic function.[197,198] Many children and adolescents with CFS have orthostatic tachycardia associated with hypotension, acrocyanosis, and peripheral edema.[199,200] Adolescents who develop CFS after infectious mononucleosis have abnormal exercise tolerance and more autonomic symptoms than recovered controls, suggesting they were predisposed to autonomic dysfunction before the illness or that the illness was particularly severe and led to autonomic dysfunction.[201,202] Moreover, improvement in symptoms over time correlates with improved measures of autonomic cardiovascular control.[203] In a matched case-control study, 50% of 26 children and adolescents with CFS and 20% of controls had orthostatic intolerance demonstrated on tilt-table test.[204] Additional evidence of autonomic dysfunction comes from the demonstration of abnormal catecholaminergic-dependent thermoregulatory responses.[205]

In the Wichita surveillance study, tilt-table testing caused orthostatic instability in 30% of adult CFS subjects and 48% of nonfatigued controls.[206] These results were particularly powerful because subjects were drawn from the general population rather than tertiary center clinics. It seems unlikely that preexisting orthostatic intolerance causes CFS; rather, the inciting event and ensuing decrease in activity may lead to deconditioning and orthostatic intolerance that is detectable in the laboratory.[204]

Early studies pointed to connective tissue disorders, which can be associated with orthostatic intolerance, in children with CFS.[207,208] A later study, however, failed to demonstrate constitutional laxity or differences in collagen metabolism in patients.[209]

Neuroendocrine and Metabolic Function

Some studies of adults with CFS suggest mild central adrenal insufficiency.[210–212] Although modest improvements have been seen with the use of low-dose hydrocortisone,[213,214] adrenal suppression outweighs the potential benefits.[213]

There may be connections among hypothalamic-pituitary axis (HPA) abnormalities, orthostatic intolerance, and immune dysfunction. It is possible that an HPA disturbance evolves over time and is related to factors such as inactivity, sleep disturbance, psychiatric comorbidity, and stress.[215] One study showed decreased salivary cortisol awakening responses in a population-based sample of CFS subjects who had experienced childhood trauma, suggesting that an HPA disturbance in CFS may have its origins before symptoms manifest.[216]

Metabolic defects in skeletal muscle also have been proposed.[217,218] At least one paper demonstrated increased oxidative stress in pediatric CFS patients.[180]

Sleep and Neurocognitive Function

Unrefreshing sleep is common among CFS patients.[219] Patients also have neurocognitive impairment, including problems with memory, difficulty expressing thoughts, paying attention and understanding, slowness of thought, and absent-mindedness.[219]

Parallels have been drawn between CFS and postpolio syndrome.[220,221] Of particular interest are reports of patients with CFS in whom punctate subcortical white matter hyperintensities were visualized on magnetic resonance imaging (MRI).[44,222,223] Some functional studies demonstrate alterations in regional cerebral blood flow and metabolic activity,[224–228] but others do not.[228] Although the significance of these findings is unclear, there is evidence of neuropsychological impairment in patients with

CFS.[229,231] Other evidence for neurobiologic alterations includes sleep disturbance[231–234] and the possibility of a central mechanism for muscle fatiguability.[235,236]

Genomics

Early studies of CFS patients suggested differential expression of genes involved in immunologic, neuronal, and mitochondrial function[237,238] and dramatic differences in exercise-responsive genes.[239] The most extensive study published examined the expression of 39,174 genes in 55 CFS patients and 75 controls[240]; 85 genes were upregulated, and 3 genes were downregulated. Seven subtypes were seen based on the pattern of gene expression, and they were associated with different clinical phenotypes.[241] In a follow-up study that included 62 additional CFS patients, there was evidence of subtype-specific relationships for EBV and enterovirus infection, consistent with the idea that these viruses can trigger CFS.[242]

Heterogeneity in CFS cohorts has made interpretation of genomic studies difficult. In an attempt to study gene expression in a more homogenous group, investigators analyzed the peripheral blood transcriptome in patients with postinfectious fatigue, comparing results within subjects (i.e., early illness vs. late recovery), between cohorts (i.e., various infectious triggers), and with controls who did not develop prolonged fatigue.[243] No genes were consistently associated with illness.

Psychology

In a population-based study, 89% of adults with CFS had at least one lifetime psychiatric diagnosis.[244] Some studies suggest that psychiatric illness is more likely to precede the onset of CFS than to follow it,[245] and a prospective birth cohort study in the United Kingdom highlighted the importance of adulthood psychopathology—and childhood adversity in a few people—in the cause of CFS.[246] Other studies show that the premorbid incidence of psychological disturbance in adults with CFS is similar to that in general medical populations[247] and that the development of prolonged fatigue is not related to initial levels of psychological stress.[248] Premorbid psychiatric disorders and psychological distress do not seem to predict prolonged fatigue after infectious mononucleosis.[249–251]

Pediatric patients with CFS have a high prevalence of anxiety and mood symptoms. As many as three fourths meet diagnostic criteria for affective disorder.[53] Longitudinal studies suggest that depression and anxiety may serve as risk factors for the development of chronic fatigue[49–51] and may predict fatigue severity.[252] Youths with CFS have higher levels of reported depression than healthy peers and those with other medical conditions.[53,58,253] Although adolescents with CFS do not report major problems with their social skills and self-esteem, they do experience diminished competence in domains such as athletics, recreational activities, and romantic involvement.[254] Adolescent patients also have difficulty identifying, labeling, and expressing affective states (i.e., alexithymia), which can lead to mood difficulties.[255]

Mood symptoms of children and adolescents with CFS are qualitatively different from those of children with clinical depression,[256] with less suicidal ideation and severe dysphoria.[257] This suggests that depressive symptoms may be a response to prolonged fatigue, associated physical symptoms, and declines in academic performance and social participation.[253] The mood problems reported by adolescents with CFS may be more accurately described as anhedonia (i.e., experiencing decreased enjoyment from previously enjoyable experiences) rather than a more globally negative mood or self-image.[53] Gene expression profiles of CFS patients are markedly different from those with endogenous depression, supporting the idea that CFS does not equal depression.[242]

Some studies show that adolescent CFS patients endorse palliative coping strategies (i.e., avoidance, distraction, escape, activity reduction, and resting) as the primary approach to symptom management.[258] School absenteeism is disproportionately higher among adolescent CFS patients than among peers with other chronic illnesses.[259,260] Patients who see a relationship between psychological factors and illness manifestation and recovery and whose parents encourage participation in activities and have higher expectations about performance have more favorable outcomes.[261]

However, parents of children with CFS tend to overestimate their child's cognitive skills, suggesting that parental expectations also may create a stressful dynamic that affects symptom maintenance and functional disability.[262]

A subset of pediatric patients with CFS exhibits qualities suggesting an eating disorder.[263] Being underweight at the time of diagnosis may be a predictor of poor outcome.[264]

Box 200.3 summarizes the most consistent findings of psychological studies of pediatric CFS.[53,58,252–267] Physicians should resist the temptation to align themselves with the organic or the psychological camp and should understand that transcendence of such mind-body dualism is crucial to effective treatment.

Box 200.3

Major Psychological Findings in Children and Adolescents With Chronic Fatigue Syndrome

Depression[a]

Somatization

Impairment in social activities

Reduced self-esteem and social competence

Anxiety

Alexithymia[b]

Anhedonia[c]

Disordered eating

Palliative coping strategies

---

[a] Depressive symptoms are less severe than in patients with endogenous depressive illness.

[b] Difficulty identifying, labeling, and expressing affective states.

[c] Decreased enjoyment from previously enjoyable experiences.

Data from references 53, 58, 252–267.

Pathogenesis

CFS is probably not caused by a unique infectious agent but instead is the final common pathway of a variety of insults, which cause a cascade of pathologic events in genetically and psychologically susceptible hosts. Associated immune dysregulation may result in inflammation and epiphenomena such as reactivation of latent viruses, all of which may contribute to fatigue and associated symptoms[268]; deconditioning sustains and magnifies the problem.

The PIFS model suggests that symptoms can be triggered by an acute infection and perpetuated in the absence of a sustained systemic inflammatory response.[144,145] Support for this model comes from the finding of gene expression pattern subtypes that are associated with infection.[241,242] The severity of the acute illness predicts PIFS, which follows relatively severe infectious syndromes such as infectious mononucleosis,[144] Lyme disease,[269] dengue,[270] viral meningitis,[271] Ross River virus infection,[144] and Q fever[144] but not minor upper respiratory infections.[272]

CFS is not strictly a psychological disorder; rather, patients may enter a cycle of attribution and avoidant behaviors after an acute illness associated with fatigue.[273] They attribute their symptoms to an external agent ("my virus") and retreat from an active lifestyle. Self-esteem is preserved because the cause is perceived to be external and beyond control. Vulnerability genes, early life experiences, and comorbid conditions may play a role in magnifying stress responses and symptoms.[192] Early childhood trauma is associated with a sixfold increased risk of CFS with neuroendocrine dysfunction, suggesting that in some patients, CFS is a disorder of adaptation promoted by early environmental insults.[216]

Avoidant behavior further reduces tolerance for physical activity, and re-exposure to activity elicits further symptoms. Intercurrent illnesses perpetuate the cycle of symptoms, attribution, avoidance, fatigue, and withdrawal. Children and adults with CFS maintain strong convictions that the fatigue is physiologic, rejecting psychological explanations.[153,273] Beliefs about medical illness correlate with functional impairment.[274–277]

Clinical Manifestations and Evaluation

The sentinel complaint is profound, debilitating, pervasive fatigue that dramatically interferes with normal activity. It begins suddenly and stands in marked contrast to the patient's previous well-being. Patients may complain that they “never recovered from that virus.” Children experience disruption in school attendance and extracurricular activities.[57,230,278]

Aside from the core symptoms of fatigue, postexertional malaise, unrefreshing sleep, cognitive impairment, and orthostatic intolerance, patients may complain of myalgia, arthralgia, feverishness (but seldom documented fever), headache, muscle weakness, sore throat, abdominal pain, lymph node enlargement or pain, dizziness, and nausea. Symptoms manifest to a pathologic degree and are continuous, but objective confirmation is often difficult.

The typical teenage patient is previously energetic, athletic, high achieving, and female. She is from an upper middle class suburban family, has been affected for many months, and has had exacerbations and remissions. Significant social, family, or interpersonal changes often predate the onset of illness. There may be a close relative with CFS. Some patients participate in usual activities but complain of exhaustion afterward, whereas others essentially are bedridden. Some patients are overcome by worry, distress, and frustration, but others are seemingly indifferent.

Outcome

The overall prognosis for adult patients is guarded.[274,279] Among adolescents, fatigue is a relatively stable complaint.[49,50] Most case series document a favorable prognosis (Table 200.1),[52,53,58–62,203,280,281] with rates of improvement ranging from 53% to 100% over a period of several years.

Management

The patient's conviction that “something is wrong” should not be dismissed, even in the face of normal physical findings and laboratory test results. However, the physician should not endorse unfounded pathogenic theories because further psychological investment in such theories can increase the patient's helplessness, frustration, and isolation.

Medical Evaluation

The initial history, physical examination, and laboratory evaluation focus on eliciting core features and discovering other possible causes for the patient's symptoms. A useful guideline for eliciting the core features of CFS is given in Table 200.2,[6] and clues to alternative diagnoses that can manifest with fatigue are listed in Box 200.4.[35,282] Suggested laboratory testing and potential alternative diagnoses are given in Box 200.5.[8,33,35] Although EBV serology has no diagnostic value in CFS, some children referred for fatigue are commercial testing packages that include, for example, immunophenotyping is unwarranted.[8]

TABLE 200.2

Eliciting Symptoms of Chronic Fatigue Syndrome in Children

Clinical Manifestation[a]	Questions to Ask	What Patients May Report
Fatigue	How fatigued are you? Does it help to rest, lie down, find a quiet place, or avoid exercise?	Flu-like fatigue and exhaustion I'm "wired but tired" (exhausted but unable to relax). I feel like a battery that is never able to recharge. Thinking takes a lot more work than it used to. My arms, legs, and body feel heavy and harder to move.
Substantial decrease or impairment in function	How much has the illness affected your ability to work, attend school, and take care of chores? What are you able to do now and how does that compare with before you became ill? Are you able to participate in extracurricular activities or sports?	Severe limitation in personal management Decline in grades or loss of job Predominantly homebound Decreased social interaction and increased isolation
Postexertional malaise	What happens after you engage in normal physical or mental exertion? How long before you feel bad? How long before you recover? What happens if you go beyond your limits? Are there activities you avoid because of your illness?	After exertion I "crash," "relapse," or "collapse." I'm mentally tired after the slightest effort. I'm physically drained or sick after mild activity. The more demanding or prolonged the activity, the more severe and prolonged the payback.
Unrefreshing sleep	Do you have any problems getting to sleep or staying asleep? How do you feel after you've slept? Do you need too much sleep? Do you nap more than other people?	I feel like I never sleep. I cannot fall asleep or stay asleep. I don't feel good after a night's sleep.
Cognitive impairment	Do you have problems driving, watching a movie, reading, completing tasks under time constraints, or following a conversation? How is your performance at school or work compared with before you became ill? Are you having problems thinking?	I feel like I have "brain fog." I'm often confused or disoriented. It's hard to concentrate and focus. I cannot process information or find the right words. I have trouble with multitasking and decision making. I've become absent-minded and forgetful.
Orthostatic intolerance	How do you feel when you've been standing still for more than 1 or 2 minutes? How do you feel when you stand	LightheadednessDizzinessSpatial disorientationFaintingFeeling dizzy, lightheaded, or unwell when sitting up or standing still for a long period of time

	up rapidly after sitting for a long time? How long can you stand still (e.g., waiting for the school bus or taking a hot shower) before feeling ill? Are your symptoms worse in hot weather? Do you study in a reclining or lying-down position? Do you prefer to sit with knees to your chest or with your legs under you?	

[a] It may be helpful for patients to keep a diary to document symptoms and activities. In addition to the listed symptoms, patients may complain of pain, describing their muscles as "constantly burning" or the head as "ready to explode." Many report a triggering infection from which they never fully recovered, and some may report more or less susceptibility to infection.

Box 200.5

Medical Laboratory Evaluation for Children With Persistent Fatigue

Tests	Primary and Alternative Diagnoses Screened For
ROUTINELY PERFORMED TESTS	
Complete blood count	Anemia, hematologic malignancy
Comprehensive metabolic panel	Electrolyte disturbance, diabetes, occult hepatopathy, renal insufficiency, eating disorder, adrenal insufficiency
Urinalysis	Chronic urinary tract infection, nephritis, nephrosis, diabetes
Thyroid-stimulating hormone and free thyroxine	Hypothyroidism
Erythrocyte sedimentation rate and C-reactive protein	Chronic infection, malignancy, autoinflammatory or rheumatologic disorders
IgA anti-endomysial antibody or IgA anti–tissue transglutaminase antibody	Gluten-sensitive enteropathy
Creatine kinase	Myopathy, myositis
Serum ferritin	Iron deficiency anemia
Epstein-Barr virus serology panel	Infectious mononucleosis[a]
OTHER TESTS (INDICATIONS)	
Serum cobalamin and folate concentration (macrocytosis)	Vitamin B_{12} or folic acid deficiency
Brucella and *Borrelia* serology (exposure history)	Chronic bacterial infection
HIV antigen/antibody test (risk factors, lymphadenopathy)	HIV infection
Hepatitis B virus and hepatitis C virus serology or nucleic acid test (risk factors, transaminase elevation)	Chronic viral hepatitis
Epstein-Barr virus, cytomegalovirus, and *Toxoplasma gondii* serology (unexplained fever, lymphadenopathy)	Reactivation of latent infection
Antinuclear antibody, rheumatoid factor, autoantibody panel (prominent joint complaints, acute phase reaction)	Rheumatologic disease
Serum immunoglobulins, total hemolytic complement, specific antibody (recurrent infections)	Primary immune deficiency
Toxicology (clinical suspicion)	Substance abuse
Cortisol levels (weakness, salt craving, hyperpigmentation)	Addison disease
TESTS NOT ROUTINELY PERFORMED	
Auditory brainstem responses	—
Electrodermal conductivity	—
Immunophenotyping	—

[a] Prolonged symptoms after acute Epstein-Barr virus–induced infectious

to the viral capsid antigen and IgG antibodies to the nuclear antigen can help to determine the time of onset and immunologic resolution of infection.

HIV, human immunodeficiency virus infection; Ig, immunoglobulin.

Modified from Fukuda K, Straus SE, Hickie I, et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. Ann Intern Med 1994;121:953–959; Royal College of Paediatrics and Child Health. Evidence based guideline for the management of CFS/ME (chronic fatigue syndrome/myalgic encephalopathy) in children and young people. 2004. http://www.rcpch.ac.uk/system/files/protected/page/RCPCH%20CFS.pdf; and National Institute for Health and Care Excellence. Chronic fatigue syndrome/myalgic encephalomyelitis (or encephalopathy): diagnosis and management. Clinical guideline CG53. 2007. http://www.nice.org.uk/guidance/CG53.

Quantification of symptoms (e.g., duration of illness, hours spent sleeping per day, changes in grades, weeks of school missed, time spent in social, sporting, or recreational activities) provides useful measurements for baseline assessment and follow-up. Documentation of illnesses or exposures preceding the onset of fatigue, provocative and palliative factors, occurrence of CFS in family members, and recent major psychosocial changes is sought. The patient's experience with healthcare providers and beliefs about diagnosis are elicited. The evaluation process helps solidify the doctor-patient relationship, assures the patient that the illness is being taken seriously, and protects the patient from unnecessary procedures.

For some patients, labeling the illness as CFS provides a sense of relief from diagnostic confusion. For others, adopting the CFS label leads to further withdrawal by focusing on illness rather than on rehabilitation.

Psychological Evaluation

Evaluation for mood and anxiety symptoms and screening for disordered eating is important, and data should be obtained from the child, parents, siblings, and teachers. A comprehensive psychological evaluation is warranted, including measures of cognitive, executive, and neuropsychological function; depression and anxiety; somatoform disorder; and family dynamics. Physicians should emphasize that any chronic condition can have psychological concomitants, and psychological services should be an integral part of assessment and treatment programs.

Therapy

Medical treatments that have been subjected to randomized or controlled clinical trials, or both, are listed in Box 200.6.[283–328] These studies have shown inconsistent results, and no medical treatment is specifically indicated for CFS. Drugs targeted at comorbidities, however, may be useful, including antidepressants for patients with depressive illness and sleep aids for patients with profound sleep disturbance. A host of unconventional therapies have been advocated for CFS, most of which have no theoretical basis for utility.

Modified from Chambers D, Bagnall A-M, Hempel, et al. Interventions for the treatment, management and rehabilitation of patients with chronic fatigue syndrome/myalgic encephalomyelitis: an updated systematic review. J R Soc Med 2006;99:506–520.

The emerging standard of care for CFS includes graded exercise programs and cognitive-behavioral therapy (CBT).[329,330] CBT is

The emerging standard of care for CFS includes graded exercise programs and cognitive-behavioral therapy (CBT).[329,330] CBT is directed at modifying maladaptive thinking and attributional patterns to enhance feelings of self-efficacy and decrease activity avoidance. Benefit has been demonstrated in adult and pediatric patients.[273,331–334] In a novel approach, Dutch investigators randomized adolescent CFS patients to an internet-based CBT program or standard care; after 6 months, improvement was seen in full school attendance (75% vs. 16%), absence of severe fatigue (85% vs. 27%), and normal physical functioning (78% vs. 20%).[335] The dramatic success of this intervention was in part attributed to the fact that patients and parents were involved, the large therapeutic dose (i.e., 255 logons per participant), the ready availability of the intervention, and the intrinsic appeal of the internet to adolescents.[336]

The importance of cognition in recovery from CFS was illustrated in a landmark study of adult patients, who were randomized to standard medical care alone or to standard care plus adaptive pacing therapy, CBT, or graded exercise therapy.[330] The latter two treatments, which were more effective, involve positive cognitive constructs (“I am able to do more than I thought I could.”) than the former (“I need to focus on how fatigued I am to stop in time.”).[337]

Supportive counseling combined with behavioral techniques and increased physical activity can be beneficial.[338] Success has been reported using a program focused on breaking the association between experiencing symptoms and stopping activity.[339] In a randomized trial, CBT was effective in reducing the severity of fatigue, improving physical functioning, and increasing school attendance.[340] Decreases in fatigue associated with CBT are associated with decreases in reported pain.[341] CBT reduced self-reported cognitive impairment but did not improve performance on specific neuropsychological tests,[342] which suggests that distorted perception of cognitive processes may be more central to CFS than actual cognitive performance.

Studies of related and overlapping conditions point to useful interventions.[343,344] The mainstay of these programs is an emphasis on improved functioning, whereas symptomatic improvement is viewed as secondary. Supported CBT strategies include training in relaxation strategies and cognitive interventions to modify and decreased activity avoidance,[340,344] increased physical activity,[338] and decreased intensity of symptoms such as headache and body aches and pains.[341]

Improvement has been seen using multidimensional cognitive-behavioral interventions in which adolescents and parents are educated in a holistic model of CFS that discourages adoption of exclusively physical or psychological models of the illness.[345] Vicious cycles that exacerbate illness are explained. Families are taught to reduce attention to and secondary gain from CFS symptoms and to promote independent use of positive coping skills. Behavioral management strategies, such as praise, rewards, and consequences, are employed to motivate the child to use coping and stress management strategies as they progress toward improved functioning.[346]

Some centers have adopted inpatient rehabilitation models, which include parent education and highly structured programs conducted over several weeks that rely on individual and group interventions. These strategies have improved overall functioning, school attendance, sleep, medication use, and emotional well-being, although improvement in fatigue symptoms has been more modest.[347–349]

Activity

Return to physical activity and schoolwork is an essential part of treatment. Excused absences from school must be time-limited and linked to gradual increases in activity and integration. Committing to gradual increases in activity and keeping formal records may engender feelings of self-efficacy and hopefulness. Clinical trials of graded exercise programs for adults have shown benefits.[350–353]

Follow-Up

Regular medical and psychological follow-up visits are an important part of treatment. Serial evaluations enable the physician to monitor for alternative, potentially treatable diagnoses and to repeat some laboratory tests as indicated. Follow-up visits allay the patient's fear of abandonment and provide reassurance through exacerbations until improvement occurs.

Viruses

OUTLINE

201 Classification of Human Viruses
DNA Viruses: Poxviridae
DNA Viruses: Herpesviridae
DNA Viruses: Adenoviridae
DNA Viruses: Adenoviridae
DNA Viruses: Hepadnaviridae
DNA Viruses: Parvoviridae
RNA Viruses: Reoviridae
RNA Viruses: Togaviridae, Flaviviridae, and Bunyaviridae
RNA Viruses: Coronaviridae
RNA Viruses: Paramyxoviridae
RNA Viruses: Rhabdoviridae
RNA Viruses: Orthomyxoviridae
RNA Viruses: Arenaviridae and Filoviridae
RNA Viruses: Retroviridae
RNA Viruses: Picornaviridae
RNA Viruses: Caliciviridae

201

Classification of Human Viruses

Robert David Siegel

The virus family concept is fundamentally important in understanding the biologic classification of viruses.[1] By specifying the family to which a virus belongs, much can be inferred about its physical, chemical, and biologic properties and its evolutionary relationships and modes of gene expression.[2] Virus families are designated with the suffix *-viridae.*[3] Families are distinguished largely on the basis of physiochemical properties, genome structure, size, morphology, and molecular processes.[4] Table 201.1 lists some criteria that are used to differentiate human virus families.

TABLE 201.1

Major Criteria for Classifying Human Virus Families

Criterion	Basis of Classification
Type of genomic nucleic acid	DNA or RNA
Nucleic acid strandedness	ds, ss, partially ds
Sense of ss nucleic acid	+, −, − with ambisense
Capsid morphology	Icosahedral, helical, or complex
Envelope	Present or absent
Genome segmentation	Number of segments
Genomic structure	For example, type of RNA cap, location of structural genes or repeat

	sequences
Electron micrographic (EM) appearance	For example, bullet-shaped rhabdoviruses or star-shaped astroviruses
Size of virion and/or genome	For example, large-genome DNA viruses (e.g., poxviruses, herpesviruses) versus small-genome viruses (e.g., picornaviruses, parvoviruses, hepadnaviruses)
Nature of gene expression, including nature and number of mRNA transcripts	For example, use of genomic polyproteins (e.g., picornaviruses, flaviviruses); use of reverse transcriptase (e.g., retroviruses, hepadnaviruses); use of multiple 3′ nested genes (e.g., coronaviruses); use of RNA ambisense coding (e.g., arenaviruses, bunyaviruses)

ds, double stranded; ss, single stranded.

The 26 virus families implicated in human disease[5] are listed in Table 201.2. In some cases, humans serve as a reservoir for the viruses and the link to human disease is clear. In other cases, humans may be incidental hosts or the link to disease may be more tenuous. Table 201.3 lists specific viruses within each family that are linked to human disease.

TABLE 201.2

Families of Viruses That Infect Humans

Family Name	Derivation of Family Name	Genome	Segmentation	Capsid Morphology	Envelope
Adenoviridae	Gland	dsDNA	1	Icosahedral	Naked
Anelloviridae	Ring-shaped	ssDNA(−)[f]	1	Icosahedral	Naked
Arenaviridae	Sand	ssRNA(−)[g,h]	2	Helical	Enveloped
Astroviridae	Star	ssRNA(+)[i]	1	Icosahedral	Naked
Bornaviridae[a]	Location in Germany	ssRNA(−)[g]	1	Helical	Enveloped
Bunyaviridae	Location in Uganda	ssRNA(−)[g,h]	3	Helical	Enveloped
Caliciviridae	Cup or chalice	ssRNA(+)[i]	1	Icosahedral	Naked
Coronaviridae[b]	Crown	ssRNA(+)[i]	1	Helical	Enveloped
Filoviridae[a]	Thread	ssRNA(−)[g]	1	Helical	Enveloped
Flaviviridae	Yellow	ssRNA(+)[i]	1	Icosahedral	Enveloped
Hepadnaviridae	Liver, DNA	Partially ssDNA	1	Icosahedral	Enveloped
Hepeviridae	*Hep*atitis E	ssRNA(+)[i]	1	Icosahedral	Naked
Herpesviridae[c]	Creeping	dsDNA	1	Icosahedral	Enveloped
Orthomyxoviridae	True, slime or mucus	ssRNA(−)[g]	6–8	Helical	Enveloped
Papillomaviridae	Bumpy, tumor	dsDNA	1	Icosahedral	Naked
Paramyxoviridae[a]	Alongside, slime or mucus	ssRNA(−)[g]	1	Helical	Enveloped
Parvoviridae	Little	ssDNA	1	Icosahedral	Naked
Picobirnaviridae	“Little”; “two”, RNA	dsRNA	2	Icosahedral	Naked
Picobirna	Little, two, RNA	dsRNA	2	Icosahedral	Naked
Picornaviridae[d]	Little, RNA	ssRNA(+)[i]	1	Icosahedral	Naked

Pneumoviridae	“Lung”	ssRNA(−)[g]	1	Helical	Enveloped
Polyomaviridae	Many, tumor	dsDNA	1	Icosahedral	Naked
Poxviridae	Pustule	dsDNA	1	Complex	Varies
Reoviridae	*R*espiratory, *e*nteric, *o*rphan	dsRNA	10–12	Icosahedral	Naked
Retroviridae	Backward	ssRNA(+)[i]	1 but diploid	Complex	Enveloped
Rhabdoviridae[a]	Rod	ssRNA(−)[g]	1	Helical	Enveloped
Togaviridae	Cloak	ssRNA(+)[i]	1	Icosahedral	Enveloped
Delta[e]	Fourth hepatitis group	ssRNA(−)[g]	1	Icosahedral	Enveloped

[a] Mononegavirales.

[b] Nidovirales.

[c] Herpesvirales.

[d] Picornavirales.

[e] Floating genus, which is not currently assigned to a viral family. It bears some similarities to viroid pathogens of plants.

[f] ssDNA(+) indicates the mRNA-coding strand.

[g] ssRNA(−) indicates the complement of the message-sense strand.

[h] Some segments are ambisense.

[i] ssRNA(+) indicates a message-sense strand.

ds, double stranded; ss, single stranded.

TABLE 201.3

Human Viral Infections Listed by Family[a]

Family Name	**Representative Viruses**[b]
Adenoviridae	Human adenovirus types 1 to 57 in seven species (human adenovirus species A to G)[28,29]
Anelloviridae[8]	Torque teno virus 1 (TTV1),[c] Torque teno mini virus 1, Torque teno midi virus 1[29] (type species for numerous viruses in 3 genera)
Arenaviridae	Lassa virus, lymphocytic choriomeningitis virus, Junin virus, Machupo virus, Guanarito virus, Sabiá virus, Whitewater Arroyo virus,[30] Chapare virus,[31] Lujo virus
Astroviridae	Human astroviruses (eight serotypes)
Bornaviridae	Mammalian 1 bornavirus (formerly Borna disease virus [BDV])[29]
Bunyaviridae	California encephalitis virus, Sin Nombre virus, La Crosse virus, Hantaan virus, Muerto Canyon virus, Crimean-Congo hemorrhagic fever virus, Sandfly fever viruses, Rift Valley fever virus, Heartland virus, and many others
Caliciviridae	Noroviruses, sapoviruses
Coronaviridae	SARS coronavirus; MERS coronavirus[29]; human coronaviruses OC43,[32] 229E, NL63,[33] and HKU1[34]; human torovirus and other human enteric coronaviruses
Filoviridae	Ebola viruses (e.g., Zaire ebolavirus, Bundibugyo ebolavirus, Reston ebolavirus, Sudan ebolavirus, Taï Forest ebolavirus),[29] Marburg virus
Flaviviridae	Genus *Alphavirus*: dengue virus, yellow fever virus, Japanese encephalitis virus, West Nile virus, Murray Valley encephalitis virus, Kyasanur

	encephalitis virus, tick-borne encephalitis virus, Zika virus, and others Genus *Hepacivirus*: hepatitis C virus (HCV) Genus *Pegivirus*[d]: GB virus-C[c] (GBV-C) (formerly hepatitis G virus [HGV])[35]
Hepadnaviridae	Hepatitis B virus (HBV)
Hepeviridae[9]	Hepatitis E virus (HEV)
Herpesviridae	Herpes simplex virus type 1, herpes simplex virus type 2, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, human herpesvirus 6, human herpesvirus 7, human herpesvirus 8 (i.e., Kaposi sarcoma-associated herpesvirus), herpes simian B virus
Orthomyxoviridae	Influenza A virus (e.g. subtype H1N1), influenza B virus, influenza C virus, Thogoto virus, Dhori virus,[36] Bourbon virus
Papillomaviridae	Human papilloma virus (>150 types with various degrees of oncogenicity)[37]
Paramyxoviridae	Measles (rubeola) virus, mumps virus, parainfluenza viruses, Hendra virus, Nipah virus, Menangle virus[38]
Parvoviridae	Human parvovirus B19, human bocavirus,[39] adeno-associated viruses[c,e]
Picobirnaviridae	Human picobirnavirus
Picornaviridae[40]	Genus *Enterovirus*: human rhinoviruses (>100 serotypes), enteroviruses (>100 serotypes, including poliovirus 1–3, coxsackievirus A and B, echoviruses, and other human enteroviruses) Genus *Hepatovirus*: hepatitis A virus (HAV) Genus *Parechovirus*: human parechoviruses Genus *Kobuvirus*: Aichi virus Genus *Cosavirus*: human cosaviruses[41] Genus *Cardiovirus*: Vilyuisk human encephalomyelitis virus, Saffold viruses[42] Genus *Salivirus*: human klassevirus,[43] salivirus A Genus *Senecavirus*: Seneca Valley virus[f] Unassigned: Syr-Darya Valley fever virus
Pneumoviridae	Respiratory syncytial virus, human metapneumoviruses
Polyomaviridae	JC virus, BK virus, KI virus, WU virus, Merkel cell polyomavirus, lymphotropic polyomavirus, human polyomavirus 6, human polyomavirus 7, trichodysplasia spinulosa-associated polyomavirus, human polyomavirus 9[44,45]
Poxviridae	Molluscum contagiosum virus, variola (smallpox) virus, monkeypox virus, vaccinia virus, orf virus, pseudocowpox virus, Tanapox virus, Yaba monkey tumor virus[46]
Reoviridae	Human rotavirus, Colorado tick fever virus, human reovirus,[c] Kemerovo virus
Retroviridae	Human immunodeficiency viruses types 1 and 2, human T-lymphocyte lymphotropic viruses,[47] xenotropic murine leukemia virus-related virus,[g] human endogenous retroviruses (HERVs), simian foamy virus
Rhabdoviridae	Rabies virus, vesicular stomatitis virus, Australian bat lyssavirus, Duvenhage virus, Mokola virus
Togaviridae	Rubella virus; Chikungunya virus; eastern equine, western equine, and Venezuelan equine encephalitis viruses; Ross River, Sindbis, and Semliki Forest viruses
Delta[h]	Hepatitis delta virus[e] (HDV)

[a] Examples listed correspond to common usage and do not necessarily comply with the official International Committee on Taxonomy of Viruses (ICTV) designations of virus species.

[b] Some zoonoses are included.

[c] Orphan virus for which a link to human disease has not been determined.

[d] Proposed genus name.

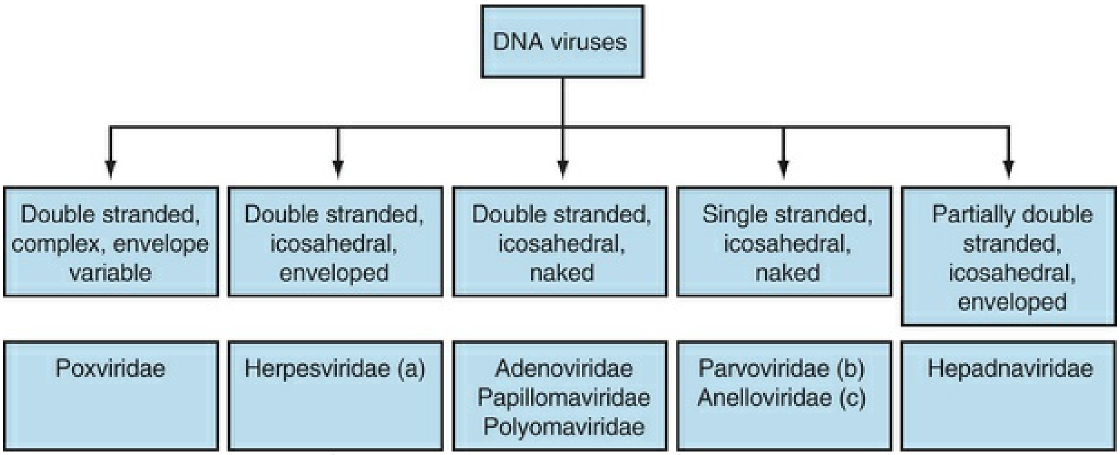
[e] Satellite virus requiring coinfection with heterologous virus for replication.

[f] Porcine virus being used clinically in humans as an oncolytic agent.[48]

[g] Possible laboratory contaminant.

[h] Floating genus, which is not currently assigned to a viral family. It bears some similarities to viroid pathogens of plants.

Facilitated by advances in molecular methods, the discovery of new viruses and more careful characterization of known viruses[6,7] have resulted in frequent changes in family taxonomy. Examples of such changes include de novo creation of a virus family (e.g., Anelloviridae),[8] splitting a new family off of an existing one (e.g., Hepeviridae from Caliciviridae),[9] dividing a family into two new families (e.g., Papovaviridae into Papillomaviridae and Polyomaviridae),[10] and uniting formerly separate families (e.g., incorporation of Toroviridae into Coronaviridae).[11,12] Working groups[13] within the International Committee on Taxonomy of Viruses (ICTV)[14] have the responsibility of approving new names and making changes in classification. Figs. 201.1, 201.2, and 201.3 illustrate the relationships among human virus families in terms of key biologic criteria listed in Table 201.1.



DNA viruses
Double stranded, complex, envelope variable
Double stranded, icosahedral, enveloped
Double stranded, icosahedral, naked
Single stranded, icosahedral, naked
Partially double stranded, icosahedral, enveloped
Poxviridae
Herpesviridae (a)
Adenoviridae
Papillomaviridae
Polyomaviridae
Parvoviridae (b)
Anelloviridae (c)
Hepadnaviridae

FIGURE 201.1 Organizational chart of the eight human virus families with DNA genomes. The chart groups virus families using the strandedness of the viral genome, the structure of the capsid, and the presence or absence of an envelope. All of these viruses are nonsegmented. Like retroviruses, hepadnaviruses contain reverse transcriptase. One family of viruses has been assigned to the Herpesvirales (a) order of viruses. Parvoviruses (b) vary in the percentage of

positive- and negative-sense single-stranded DNA (ssDNA) genomes that are packaged, depending on the genus. Anelloviruses (c) package negative-sense ssDNA genomes; this strand is transcribed into mRNA.

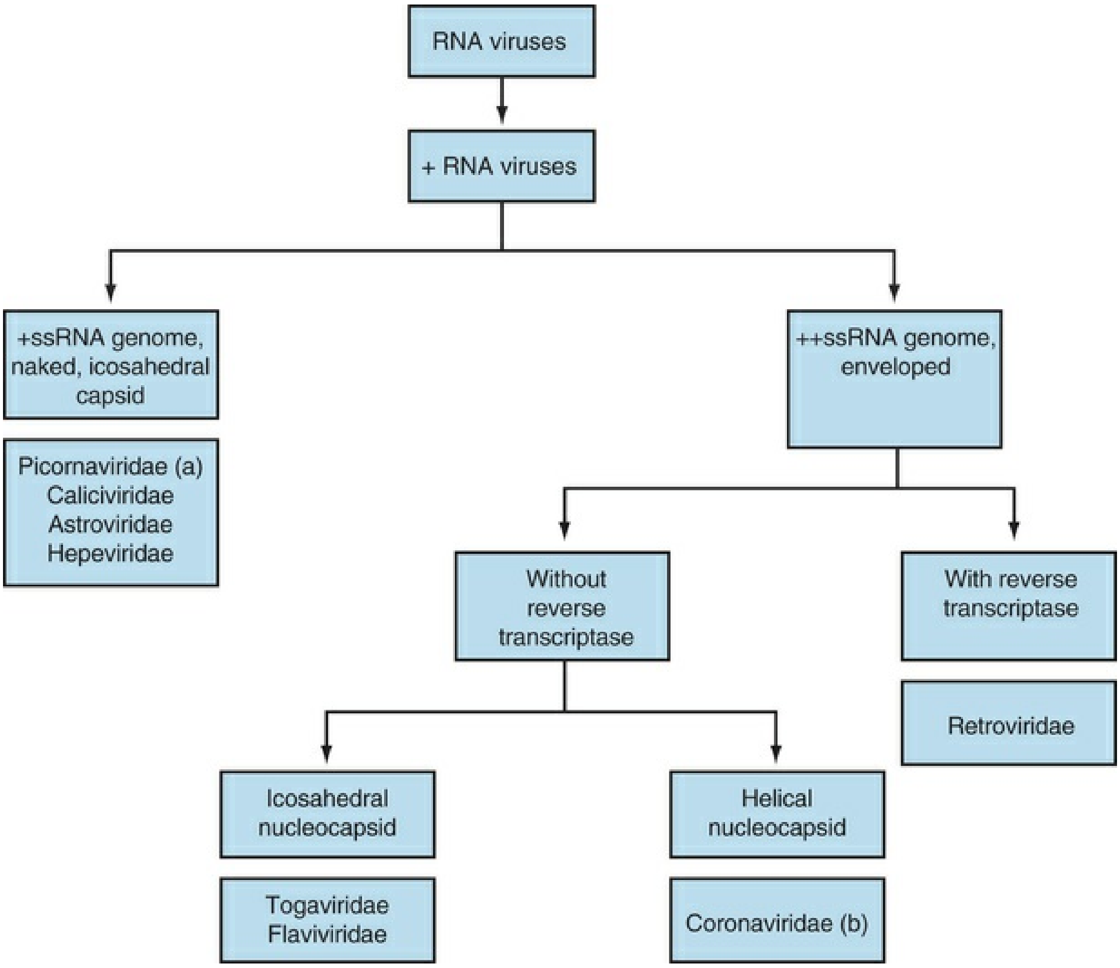


FIGURE 201.2 Organizational chart of the eight human virus families with positive-sense (+) RNA (i.e., mRNA-like) genomes. The chart groups virus families using the presence or absence of an envelope, the presence of reverse transcriptase, and the structure of the capsid. All of these viruses have a single-stranded (ss), nonsegmented viral genome. One family of viruses (a) has been assigned to the Picornavirales order of viruses. Another family of viruses (b) has been assigned to the Nidovirales order of viruses.

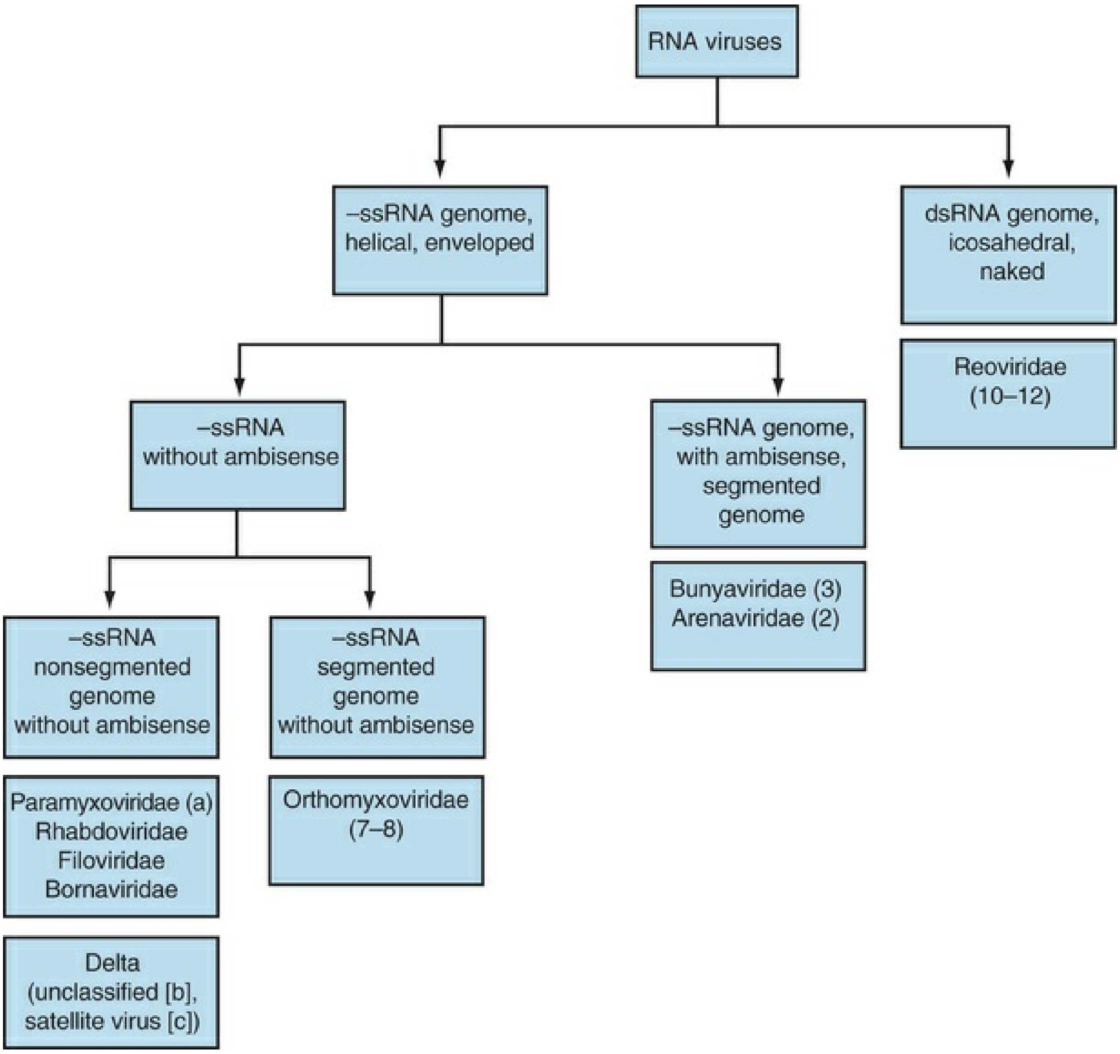

RNA viruses
–ssRNA genome, helical, enveloped
dsRNA genome, icosahedral, naked
Reoviridae (10–12)
–ssRNA without ambisense
–ssRNA genome, with ambisense, segmented genome
Bunyaviridae (3)
Arenaviridae (2)
–ssRNA nonsegmented genome without ambisense
–ssRNA segmented genome without ambisense
Paramyxoviridae (a)
Rhabdoviridae
Filoviridae
Bornaviridae
Orthomyxoviridae (7–8)
Delta (unclassified [b], satellite virus [c])

FIGURE 201.3 Organizational chart of the remaining eight human RNA virus families, including the negative (−) singled-stranded (ss) (i.e., complementary to message sense) and double-stranded (ds) RNA viruses. The chart groups the families using the structure of the genome, presence or absence of an envelope, and the presence or absence of ambisense gene expression. For segmented viruses, the number of genome segments is listed in parentheses. One group of virus families (a) is assigned to the Mononegavirales (i.e., monosegmented and negative-stranded) order of viruses. The unclassified or floating genus (b) is not currently assigned to a viral family. It bears some similarities to viroid pathogens of plants. Satellite virus (c) refers to the fact that hepatitis D virus (HDV) depends on HBV, a genomically unrelated virus, for its successful replication.

Next-generation nucleic acid sequencing has facilitated rapid and massive screening of samples obtained from healthy individuals, patients, nonhuman organisms, and environmental sources, resulting in the ongoing discovery of numerous viruses.[15,16] The clinical significance of most of these viruses has yet to be established. Advances in understanding the human microbiome are providing insights into the impact of microbial viruses in causing or modulating human disease. A well-characterized example is the role of *Vibrio cholerae* phage CTXψ in producing the clinical symptoms of cholera.[17]

Families hierarchically are subdivided in a variety of ways, including into subfamilies (suffix *-virinae*), genera (suffix *-virus*), and species (suffix *-virus*).[18] In the past, the conventions for naming species were somewhat arbitrary and varied from family to family. The ICTV has instituted a more uniform system. A virus species, as defined by van Regenmortel, is "a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecologic niche."[19] *Polythetic* refers to the fact that viruses grouped within a species share many properties. Species criteria may include genetic structure, sequence homology, host range, tissue tropism, biologic reservoir, route of transmission, immunologic cross-reactivity, epidemiology, and pathogenicity.[20] With the advent of rapid nucleic acid sequencing, sequence homology has taken precedence over other species classification criteria.[21]

The current system of species classification does not always correspond to common usage or historical concepts of species. For example, the three immunologically distinct viruses targeted by the trivalent poliovirus vaccine are considered to be the same species: human enterovirus C.[22,23] This species includes at least 23 additional serotypes with diverse clinical presentations, as well as circulating recombinant forms.[24] The practicality of distinguishing serotypes is emphasized by the eradication of wild poliovirus type 2 in 2000[25] and wild poliovirus type 3 in 2012.[26] Species can be subdivided further into groups, clades, types, subtypes, serotypes, variants, and isolates, depending on the family involved and the degree of similarity. Selected representatives called *type viruses* may be used to illustrate the properties of a particular taxon.

A number of virus families are assigned to higher-level orders, which are designated with the suffix *-virales*. Examples are Herpesvirales, Mononegavirales, Picornavirales, and Nidovirales.[27]

They are indicated by footnotes in Table 201.2. Most families are unassigned to orders.

In addition to biologic classification, viruses often are categorized according to their clinical presentation (i.e., syndromic classification), epidemiology, or mode of transmission. Box 201.1 lists the major routes of transmission for human diseases, with representative examples of viruses transmitted by each route.

Box 201.1

Common Routes of Virus Transmission to Humans

Respiratory route (i.e., droplet, aerosol, and respiratory secretions on the hands and elsewhere; oral exchange): influenza virus, varicella-zoster virus, human rhinovirus, human adenovirus, respiratory syncytial virus, parainfluenza virus, metapneumovirus

Fecal-oral route: polioviruses, coxsackieviruses, hepatitis A virus, rotavirus, astrovirus, norovirus

Direct contact: human papillomavirus (HPV), molluscum contagiosum, herpes simplex virus type 1 (HSV-1)

Sexual: human immunodeficiency virus type 1 (HIV-1), human T-lymphotropic virus type 1 (HTLV-1), hepatitis B virus (HBV), human papillomavirus types 16 and 18 (HPV-16, HPV18), HSV-2

Urine-associated: cytomegalovirus (CMV)

Parenteral route (i.e., blood and blood products, transplantation, tattooing, and scarification): HIV-1, HBV, hepatitis C virus (HCV)

Animal bite: rabies virus, Duvenhage virus

Vertical route (e.g., germline, intrauterine, perinatal, human milk): HIV-1, HTLV-1, germline transmission of endogenous retroviruses

Arthropod-borne route (e.g., mosquitos, ticks, sandflies): Japanese encephalitis virus, West Nile virus, dengue virus, yellow fever virus, Zika virus, chikungunya virus, and many others

Rodent-associated transmission: Lassa fever virus, sin nombre, and other hanta viruses (e.g., Hantaan virus, Seoul virus, and Puumala virus)

Bat-associated transmission: rabies virus, Nipah virus, Ebola virus, severe acute respiratory syndrome coronavirus (SARS CoV)

Monkey-associated transmission: herpes B virus, monkeypox virus, orf virus

Other zoonotic associations (e.g., cows, sheep): orf virus, cowpox virus

Understanding virus classification can lead to important generalizations regarding the prevention and treatment of viral infection and insights into the distribution and evolution of viruses. In addition, insights from viral taxonomy play key roles in preventing and staunching the spread of viral disease at the population level.

DNA Viruses: Poxviridae

OUTLINE

202 Poxviridae

202

Poxviridae

Brett W. Petersen

Despite the eradication of smallpox, several poxviruses remain clinically significant, including vaccinia (i.e., virus used for smallpox vaccination), molluscum contagiosum, and several relatively uncommon zoonotic viruses. Concern about smallpox as a bioterrorist weapon also has led to continued interest in poxvirus research. Concurrently, interest in poxviruses (vaccinia virus in particular) as vaccine vectors and potential immunotherapeutic agents has contributed to a rapid expansion of knowledge regarding poxvirus genetics and pathogenesis.[1,2]

Poxviruses are the largest and most complex viruses infecting humans. Virions are 220 to 450 nm long and have a characteristic brick-shaped appearance on electron microscopy (except the ovoid parapoxviruses).[3] The genome consists of linear, double-stranded DNA ranging from 130 to 375 kbp. Four genera within subfamily Chordopoxvirinae contain recognized human pathogens (Table 202.1).

TABLE 202.1

Poxvirus Diseases of Humans

Genus and Species	Clinical Syndrome	Lesion Type	Frequency	Geography	Animal Vectors
ORTHOPOXVIRUS					
Variola virus	Febrile rash illness (smallpox)	Vesicopustular	Eradicated	Laboratory only	None
Monkeypox virus	Febrile rash illness (monkeypox)	Vesicopustular	Rare	West-central Africa,	Rodent, monkey

				United States[a]	
Vaccinia virus	Localized skin lesions	Vesicopustular	Rare	Worldwide	Cattle, milking buffalo
Cowpox virus	Localized skin lesions (cowpox)	Vesicopustular	Rare	Eurasia	Rodent, cat, cow, others
MOLLUSCIPOXVIRUS					
Molluscum contagiosum	Multiple skin lesions	Epidermal hyperplasia	Common	Worldwide	None
PARAPOXVIRUS					
Orf virus	Localized skin lesions (orf, ecthyma contagiosum)	Proliferative	Rare	Worldwide	Sheep, goat
Pseudocowpox virus	Localized skin lesions (milker's nodules, pseudocowpox, paravaccinia)	Proliferative	Rare	Worldwide	Dairy cow
Bovine papular stomatitis virus	Localized skin lesions	Proliferative	Rare	Worldwide	Calves, beef cattle
Deerpox virus, sealpox virus	Localized skin lesions	Proliferative	Rare	Variable	Various
YATAPOXVIRUS					
Tanapox virus	Localized skin lesions	Nodular	Rare	East-central Africa	Monkey
Yaba-like disease virus **(of monkeys),** *Yaba monkey tumor virus*	Localized skin lesions	Nodular	Rare	West Africa	Monkey

[a] Single outbreak in Midwestern United States, 2003.

Poxviruses share several features. All poxviruses replicate in the cytoplasm, and their genes therefore encode the proteins necessary for replication.[4] Poxviruses are notable for their ability to evade or subvert the host immune system. Several poxviruses encode proteins that mimic or inhibit mediators of the host inflammatory response.[5–7] Poxviruses exhibit various degrees of tropism for host species and cell types through mechanisms that are not completely understood.[8,9]

Variola and Vaccinia

Epidemiology

Variola, the virus causing smallpox, is among the most feared viruses in human history. Smallpox has had a tremendous impact on human civilizations throughout history. Significant milestones are summarized in Box 202.1. Currently, smallpox is primarily a concern because of its use as a potential weapon of bioterrorism.

Box 202.1

History of Smallpox (Variola Virus)

10,000 BC	Smallpox postulated to emerge in early northeast African settlements from unknown source
1580–1100 BC	Three Egyptian mummies (including Ramses V) interred with possible smallpox lesions
340 AD	First reliable descriptions of smallpox appear in Chinese writings
1500s	Smallpox spread to New World by Europeans
1600–1800s	Severe smallpox epidemics occur globally
1763	Smallpox intentionally used against Native Americans during French and Indian Wars
1949	Last United States smallpox outbreak occurs in Texas
1959	World Health Assembly (WHA) resolves to undertake global eradication of smallpox
1967	World Health Organization (WHO) Intensified Smallpox Eradication Programme commences using surveillance and containment strategy
1977	Last naturally occurring case of smallpox occurs in Somalia
1978	Laboratory accident in United Kingdom results in last smallpox case (and fatality)
1979	WHO Global Commission for the Certification of Smallpox Eradication declares global eradication of smallpox; report accepted by WHA in 1980
1987	WHO sets first target date for destruction of remaining variola virus stocks in United States and Russia
1999	Former deputy director of Soviet bioweapons program alleges that USSR engaged in large-scale weaponization of smallpox virus
2002, 2014	WHO indefinitely extends target for variola destruction

Modified from Long SS. Smallpox bioterrorism. In: Long SS, Pickering LK, Prober CG (eds). Principles and Practice of Pediatric Infectious Diseases, 2nd ed. Philadelphia, Churchill-Livingstone, 2003, p. 1559.

Smallpox is a human disease. The lack of an animal reservoir and the availability of an effective intervention to prevent transmission of the virus (i.e., smallpox vaccine) were critical factors allowing eradication. Smallpox spreads by respiratory droplets, with transmission typically resulting from close or prolonged contact. In pre-eradication studies, 37% to 88% of unvaccinated household members developed smallpox after contact with a known case, compared with 90% for measles and pertussis.[3,10–12]

Acquisition of variola infection usually occurs through the respiratory tract. Skin and eye inoculation and transplacental spread also have been documented.[3] The incubation period averages 10 to 14 days, with a range of 7 to 19 days.[3,13,14] During incubation, the virus replicates in the upper respiratory tract and reaches the reticuloendothelial system through a transient primary viremia. Most virus transmission occurred during the first 7 to 10 days after lesion onset because the highest amount of viral shedding occurred during this period.

Vaccinia is the virus used for smallpox vaccination. Its origins are unclear; phylogenetic analysis indicates that it was not recently derived from variola or cowpox.[2–4] Eradication of smallpox using the smallpox vaccine is among the greatest achievements in public health.

Vaccinia has a broader host range than most poxviruses, which has allowed it to be used as a model for smallpox infection in laboratory animals. Certain strains have become enzootic in sylvatic animal reservoirs, resulting in occasional zoonotic transmission.[15–19] These infections usually are localized and self-limited.

Clinical Manifestations

Smallpox begins abruptly with a prostrating febrile prodrome characterized by high fever, chills, headache, backache, vomiting, and severe abdominal pain. In ordinary-type smallpox infections, the first lesions appear in the oropharynx 1 to 4 days after the onset of fever. Skin lesions develop first on the face or forearms and then spread to the rest of the body. The highest concentration of lesions is on the face and distal extremities. The palms and soles commonly are involved. Lesions develop slowly from macules to papules to vesicles to pustules, with each stage lasting approximately 2 days. Lesions on any one part of the body are characteristically in the same stage of development at any given time. Crusting of lesions is usually complete within 2 to 3 weeks after the onset of rash.[3]

Variola major produced several distinct clinical syndromes and had an overall mortality rate of about 30%.[13,20] The mortality rate was higher for very young children.[3] Approximately 90% of cases in the largest series were ordinary smallpox, characterized by round, firm, well-circumscribed pustules 7 to 10 mm in diameter.[20] The mortality rate was approximately 10% for patients with discrete lesions and 60% for patients with confluent lesions.[20] Less common clinical presentations were characterized by flat or hemorrhagic lesions and were associated with case-fatality rates greater than 90%. Modified smallpox (i.e., 2% of unvaccinated and 25% of vaccinated cases) was similar to ordinary smallpox but had a milder and more accelerated course. Fever and other constitutional symptoms without rash (i.e., variola sine eruptione) occurred in rare instances.[3,20]

Variola minor (alastrim) usually produced milder disease. It rarely was fatal.

Laboratory Findings and Diagnosis

To aid those evaluating patients with rash illnesses that are suspected to be smallpox, the Centers for Disease Control and Prevention (CDC) and collaborating organizations created an algorithm based on the clinical features of ordinary smallpox. Three major criteria and five minor criteria are combined to assess the risk of smallpox (i.e., low, medium, or high risk) (Box 202.2). Specific diagnostic measures are recommended based on the risk level (Fig. 202.1).

Box 202.2

Major and Minor Smallpox Criteria and Risk of Smallpox

Major Smallpox Criteria

Febrile prodrome: occurring 1–4 days before rash onset; fever ≥101°F (38°C) and at least one of the following: prostration, headache, backache, chills, vomiting, or severe abdominal pain

Classic smallpox lesions: deep-seated, firm or hard, round, well-circumscribed vesicles or pustules; as they evolve, lesions may become umbilicated or confluent

Lesions in same stage of development: on any part of the body (e.g., face, arm), all the lesions are in the same stage of development (i.e., all are vesicles or all are pustules)

Minor Smallpox Criteria

Centrifugal distribution: greatest concentration of lesions on face and distal extremities

First lesions on the oral mucosa or palate, face, or forearms

Patient appears toxic or moribund

Slow evolution: lesions evolve from macules to papules to pustules over days (each stage lasts 1–2 days)

Lesions on the palms and soles

Risk of Smallpox

High Risk of Smallpox (Report Immediately)

Febrile prodrome *and*

Classic smallpox lesion *and*

Lesions in same stage of development

Moderate Risk of Smallpox (Urgent Evaluation)

Febrile prodrome *and*

One other MAJOR smallpox criterion

or

Febrile prodrome *and*

≥4 MINOR smallpox criteria

Low Risk of Smallpox (Manage as Clinically Indicated)

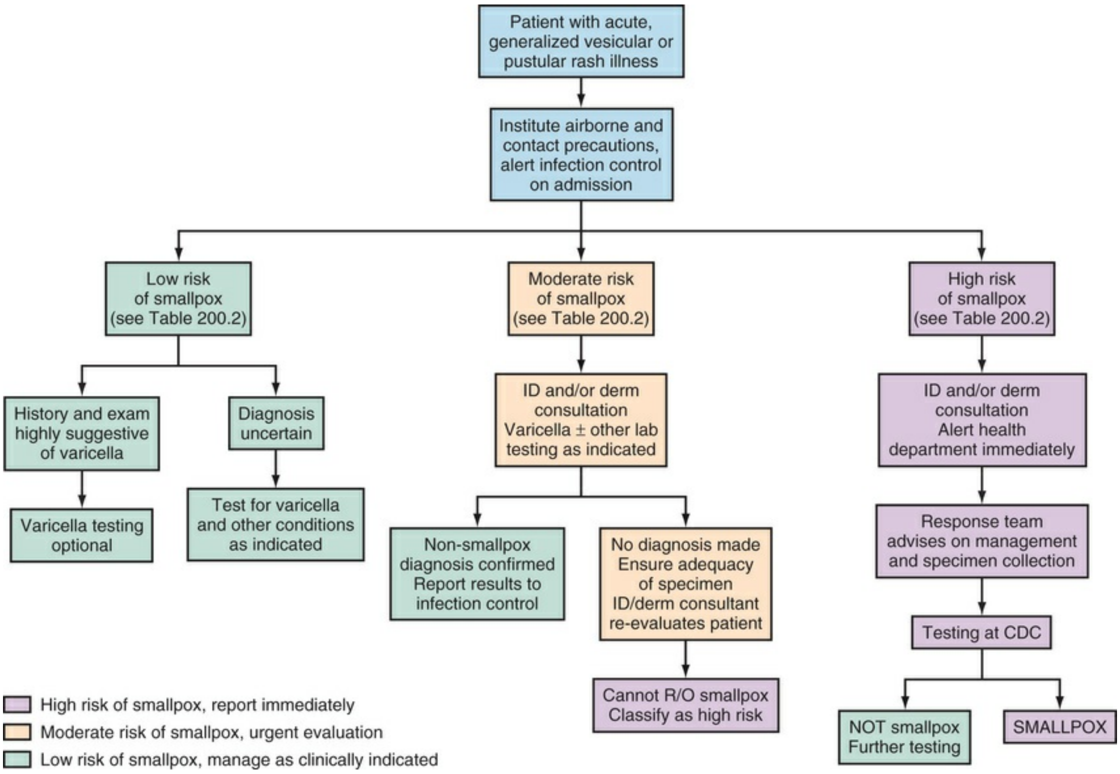
No febrile prodrome

or

Febrile prodrome *and*

<4 MINOR smallpox criteria

From Centers for Disease Control and Prevention. https://emergency.cdc.gov/agent/smallpox/diagnosis/evalposter.asp.



Patient with acute, generalized vesicular or pustular rash illness
Institute airborne and contact precautions, alert infection control on admission
Low risk of smallpox (see Table 200.2)
Moderate risk of smallpox (see Table 200.2)
High risk of smallpox (see Table 200.2)
History and exam highly suggestive of varicella
Diagnosis uncertain
Varicella testing optional
Test for varicella and other conditions as indicated
ID and/or derm consultation Varicella ± other lab testing as indicated
Non-smallpox diagnosis confirmed Report results to infection control
No diagnosis made Ensure adequacy of specimen ID/derm consultant re-evaluates patient
Cannot R/O smallpox Classify as high risk
ID and/or derm consultation Alert health department immediately
Response team advises on management and specimen collection
Testing at CDC
NOT smallpox Further testing
SMALLPOX
High risk of smallpox, report immediately
Moderate risk of smallpox, urgent evaluation
Low risk of smallpox, manage as clinically indicated

FIGURE 202.1 Algorithm for evaluating patients for smallpox. ID, infectious diseases; CDC, Centers for Disease Control and Prevention; derm, dermatologic; exam, examination; lab, laboratory; R/O, rule out.

(Modified from Centers for Disease Control and Prevention. https://www.cdc.gov/smallpox/clinicians/algorithm-protocol.html.)

Laboratory testing for variola is not recommended for low- or moderate-risk cases in the absence of known circulating smallpox.[21] The positive predictive value of these tests is extremely low, and the public health implications of false-positive results could be considerable.[22,23] If undertaken, laboratory diagnostic testing for variola virus is available through the Laboratory Response Network (LRN) with confirmatory testing by the CDC.[24] Polymerase chain reaction (PCR) testing is the preferred method for laboratory confirmation, although electron microscopy, serology, and other methods may be useful for diagnosis.[25] CDC guidelines for laboratory testing of suspected smallpox cases are available at https://www.cdc.gov/smallpox/lab-personnel/index.html.

Illnesses that can be confused with smallpox are listed in Box 202.3. Chickenpox is the illness most commonly confused with smallpox. Important features useful in distinguishing these two diseases are listed in Table 202.2. Monkeypox also can be difficult to distinguish from smallpox in the absence of epidemiologic clues, although lymphadenopathy is more prominent with monkeypox.[3]

Box 202.3

Exanthems That Can Be Confused With Smallpox by Stage

Macular or Papular

Measles

Rubella

Drug eruptions

Secondary syphilis

Erythema multiforme

Scabies or insect bites

Acne

Scarlet fever

Vesicular or Pustular

Chickenpox

Disseminated herpes zoster

Disseminated herpes simplex virus

Drug eruptions

Contact dermatitis

Erythema multiforme (including Stevens-Johnson syndrome)

Enteroviral infections

Secondary syphilis

Acne

Generalized vaccinia

Monkeypox

Impetigo

Scabies or insect bites

Disseminated molluscum contagiosum

TABLE 202.2

Features Distinguishing Smallpox From Chickenpox

Feature	Smallpox	Chickenpox
Prodromal symptoms	Frequent, severe	Infrequent, usually mild
Mature lesion morphology	Firm, well-circumscribed pustules	Superficial vesicles
Lesion development	Same stage on any one part of body	Different stages on any one part of body
Lesion distribution	Centrifugal	Centripetal
Location of first lesions	Mouth, face, forearms	Face, trunk
Patient appearance	Often toxic or moribund	Rarely toxic or moribund
Lesion evolution	Slow; 1–2 days per stage	Rapid; <24 hours per stage
Palmar/plantar lesions	Frequent	Rare

Treatment

Before eradication, treatment of smallpox largely was supportive. Vaccination of contacts within the immediate postexposure period can prevent or modify disease.[10–12,26] Cidofovir inhibits the poxvirus DNA polymerase and has proved effective against other poxvirus infections in humans[27] and against lethal orthopox virus infections in animal models.[28,29] A newer lipid ester derivative of cidofovir (i.e., CMX-001) with improved oral bioavailability and decreased renal toxicity has proved effective against orthopoxvirus infections in animal models.[30–33]

Another orally bioavailable compound (i.e., ST-246) that prevents release of virus from infected cells has proved effective against orthopoxvirus infections (including variola) in vitro and in animal models.[34–37] Evidence from animal studies suggests that these compounds can function synergistically for treatment or prevention of orthopoxvirus infections.[38,39] Development of anti-orthopoxvirus therapeutics remains an active area of research.[40,41]

Prevention

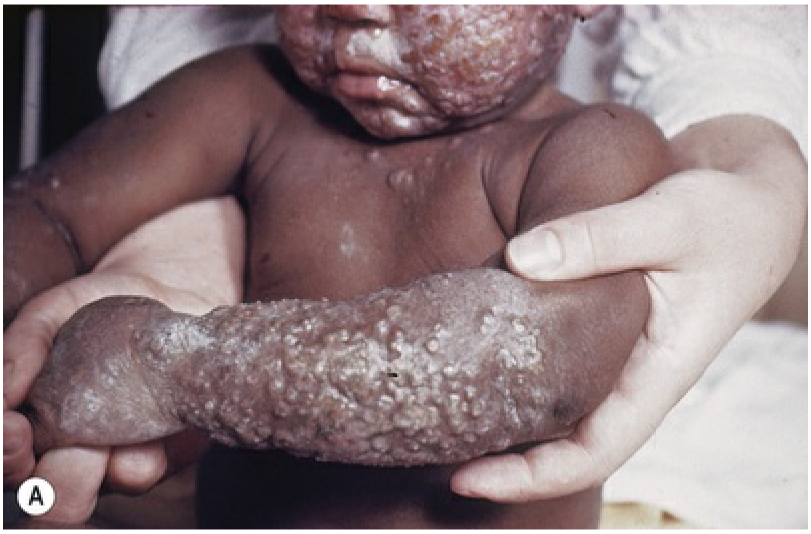
Several types of smallpox vaccine have been developed. First-generation vaccines contain live vaccinia grown in animals and then purified and treated to ensure stability.[3] Second-generation vaccines are single clones that have been isolated and grown in cell culture. They are usually similar to first-generation vaccines with regard to safety and immunogenicity.[42]

Third-generation vaccines are single clones further attenuated by serial passage or genetic manipulation. These vaccines appear to be safer than earlier vaccines, particularly among persons at high risk for severe adverse events such as those with human immunodeficiency virus (HIV) infection.[43–47] Third-generation vaccines protect against orthopoxvirus infection in animal models[44,48–50] and attenuate response to first-generation vaccines in humans,[51,52] but their ability to protect against smallpox has not been documented. Moreover, evidence suggests that third-generation vaccines may be less immunogenic than first-generation vaccines.[44,53] Subunit and DNA-based vaccines have shown promise in animal models.[54–59]

The first-generation vaccine that was used in the United States until recently (Dryvax, Wyeth) was derived from the New York City Board of Health (NYCBOH) strain, one of the strains recommended by the World Health Organization (WHO) during the eradication campaign.[3] A second-generation vaccine derived from the NYCBOH virus (ACAM2000, Sanofi Pasteur) was licensed in 2007[42,60] and has replaced Dryvax in the United States for ongoing vaccination and emergency use.[61] A third-generation smallpox vaccine (Imvamune, Bavarian Nordic) has been purchased for emergency use in persons with certain medical conditions placing them at high risk for adverse events after vaccination.[62]

First- and second-generation smallpox vaccines are delivered by multiple punctures with a bifurcated needle. Normally, a papule appears 3 to 4 days after inoculation and progresses to a vesicle and then a pustule, which crusts and separates by approximately 12 days after vaccination. Virus can be recovered from vaccination sites for 3 weeks or more if a lesion is still present. Covering the site with a porous bandage (e.g., gauze) is recommended.[63] Fever, local swelling, headache, and nonspecific rashes are common after vaccination. Images of a normal vaccination response and selected adverse reactions are available at https://emergency.cdc.gov/agent/smallpox/smallpox-images.

Severe adverse events include postvaccinial encephalitis, progressive vaccinia, eczema vaccinatum, and fetal vaccinia.[64] Generalized vaccinia occurs more commonly and is usually self-limited. Accidental inoculation of self or others (Fig. 202.2) (including ocular inoculation) can occur.[64,65] Myocarditis and pericarditis of unclear pathogenesis occurred more frequently than expected among those vaccinated in the United States since 2002.[66–68]



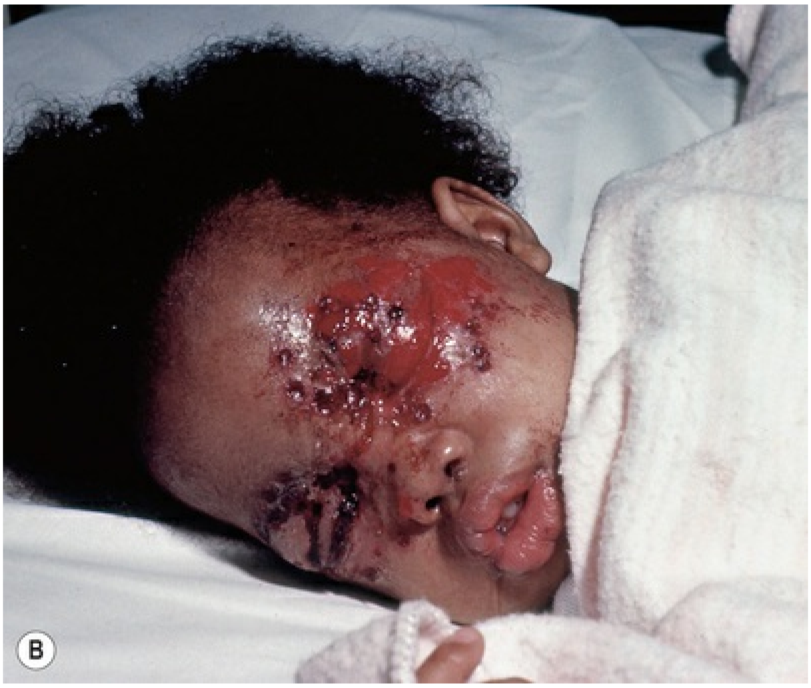


FIGURE 202.2 (A) A 6-month-old infant developed eczema vaccinatum after exposure to his vaccinated sibling. (B) An 18-month-old toddler had accidental self-inoculation of his eye and face. (Cases from Philadelphia in the 1960s. Courtesy of S.S. Long, MD.)

Vaccinia immune globulin (VIG) is indicated for certain adverse reactions, and it is available from the CDC.[69] Orally bioavailable antiviral agents hold promise for the treatment of certain vaccine complications.[70] CMX-001 and ST-246 have been used to treat severe human cases of eczema vaccinatum and progressive vaccinia, although the contributions of the individual agents is difficult to assess given the multitude of therapeutic interventions employed.[71,72]

In the absence of known circulating smallpox, vaccination is contraindicated for those with atopic dermatitis or other exfoliative skin conditions, those with diseases or treatments causing immunosuppression, pregnant women, and those with household members in any of these groups. Vaccination also is contraindicated for breastfeeding women, children younger than 12 months of age, persons with previous allergy to the vaccine, and those with moderate or severe illness or cardiac disease. Nonemergent vaccination of children younger than 18 years is not recommended by the Advisory Committee on Immunization Practices (ACIP).[73]

Zoonotic Poxviruses

Epidemiology

Four orthopoxviruses cause zoonotic infections: vaccinia, monkeypox, cowpox, and Akhmeta virus. Vaccinia and Akhmeta viruses cause sporadic human disease after exposure to infected bovine species.[74,75] Monkeypox and cowpox have been reported increasingly during recent years, possibly reflecting a decline in population-level immunity to orthopoxviruses after the end of the smallpox eradication campaign.[76,77]

Because of its similarity to smallpox, monkeypox was not recognized as a cause of human illness until 1970, 3 years after the start of the WHO's intensified smallpox eradication program.[78] Before 2003, monkeypox was limited to parts of central and western Africa, where it is endemic in several species of small mammals.[79] In 2003, an outbreak of human monkeypox in the United States resulted in 47 confirmed or probable cases.[80] The outbreak was linked to prairie dogs that had been housed with exotic animals shipped from Ghana.[81]

Genomic analysis has confirmed the existence of two monkeypox clades: Congo Basin and West African. Morbidity, mortality, and transmissibility rates are higher among persons infected with the Congo Basin clade.[82] Studies of African outbreaks indicate that 8% to 15% of unvaccinated household contacts develop infection.[78,83]

Cowpox is an emerging infection currently limited to Europe and Central Asia, where it is endemic in several species of rodents.[84–86] Despite the name, infection is most commonly contracted from domestic cats. Transmission from rats and other animals also has been reported.[86–88]

Several parapoxviruses also cause zoonotic infections. The most frequently reported is orf, also known as ecthyma contagiosum or contagious pustular dermatitis. Orf is contracted by exposure to saliva of infected sheep or goats.[89,90] Bovine papular stomatitis (caused by the bovine papular stomatitis virus) and milker's nodules or pseudocowpox (caused by the paravaccinia virus) are clinically identical to orf but occur after exposure to cattle.[3,91] Several other parapoxviruses cause human disease, including several newly discovered parapoxviruss.[18,92–94]

Tanapox is a mild zoonotic illness endemic to equatorial Africa. Only five cases have been reported in the United States, and all infected patients had recently traveled to endemic areas or were exposed to laboratory animals.[95] Epidemiologic evidence suggests transmission from nonhuman primate hosts by an arthropod vector or, rarely, by direct contact.[96,97] Two other yatapoxviruses have caused localized skin lesions in animal handlers.[25]

Clinical Manifestations

Clinically, monkeypox begins with a smallpox-like prodrome after a 10- to 14-day incubation period. The rash is similar to smallpox, but it usually is less extensive. Lymphadenopathy is prominent and may be useful in distinguishing monkeypox from smallpox.[3] Monkeypox is more common and more severe among children. Of 247 cases in Zaire between 1970 and 1984, 98% of severe cases and 100% of fatalities occurred in children.[3] Overall case-fatality rates range from 0% to 11%.[3,78,81,83,98]

Cowpox infection manifests with lesions similar to those occurring after smallpox vaccination. Lesions develop at sites of inoculation approximately 7 days after exposure, usually in association with localized lymphadenopathy, fever, and malaise. Eschars form after the lesions crust, and residual scarring is common. Cowpox has been mistaken for cutaneous anthrax, although anthrax lesions evolve more rapidly and usually are not painful.[84] Cowpox is usually mild and self-limited, although disseminated disease and fatalities have been reported among patients with atopic dermatitis.[99,100]

The lesions of orf, bovine papular stomatitis, and milker's nodules or pseudocowpox develop at the site of exposure (usually hands or arms) after a 3- to 7-day incubation period and classically progress over 14 to 72 days.[91,101] Fever, regional lymphadenopathy, and erythema multiforme can occur. Severe or widespread lesions have been reported in immunocompromised patients.[102,103]

Yatapox infections manifest with fever and other systemic symptoms that usually precede skin lesions by 1 to 4 days. Lesions are solitary in more than 75% of cases. They are characterized by slow evolution from macule to papule to nodule (with frequent ulceration), and they often are accompanied by regional lymphadenopathy.[95,96]

Laboratory Findings and Diagnosis

Monkeypox can be difficult to distinguish from chickenpox.[104] Lesion characteristics and animal exposure history are critical factors in diagnosing and differentiating localized zoonotic poxvirus infections. Laboratory diagnostic options include PCR, serology, electron microscopy, and histopathology.[89,90,95,105]

Treatment

Treatment for monkeypox primarily is supportive, although antiviral drugs can be considered.[106] Cidofovir, CMX-001, and ST-246 have proved effective against monkeypox, vaccinia, and cowpox in animal models, but human data are lacking.[27,28,29,,31,35,36,107] Parapoxvirus and yatapoxvirus infections are self-limited in most cases. Treatment of orf with topical cidofovir or topical imiquimod has been reported to be effective, although no data from controlled trials are available.[102,103,108] Excision and even amputation have been required in severe cases among immunocompromised patients.[103]

Prevention

The likelihood of acquiring a zoonotic poxvirus infection can be decreased by observing appropriate hygiene measures around animals and by limiting exposure to ill or exotic animals. Smallpox vaccination is effective in preventing monkeypox transmission, and vaccination after exposure may prevent or ameliorate disease.[78,106] Antiviral prophylaxis also has proved effective in animal models.[31,38]

Molluscum Contagiosum

Epidemiology

Molluscum contagiosum is a common infection worldwide. Incidence is highest among children younger than 5 years and those with atopic dermatitis.[109] Transmission results from direct contact or through fomites such as towels. Molluscum contagiosum can be spread by sexual contact, with resulting lesions on the genitalia, inner thighs, and abdomen. Autoinoculation is common, particularly in individuals with conditions that compromise the epidermal barrier. Autoinoculation is thought to be the most common cause of lesions on the genitalia of infants and young children. However, the possibility of sexual abuse should be considered.[110] Vertical transmission also has been reported.[111]

The incubation period varies from 2 weeks to 6 months. Molluscum contagiosum has been associated with outbreaks,[112] but it usually occurs sporadically.

Clinical Manifestations

Infection results in multiple, small (1 to 5 mm), umbilicated papules that are pearly white or flesh colored. In approximately 10% of cases, localized eczematous dermatitis (i.e., molluscum dermatitis) develops around a molluscum papule.[113] Four clinically indistinguishable subtypes have been identified, with molluscum contagiosum virus type 1 (MCV1) predominating.[109]

Molluscum contagiosum is a common opportunistic infection in patients with acquired immunodeficiency syndrome (AIDS), cancer, or neutropenia, and it can be problematic in primary immunodeficiency syndromes, especially hyperimmunoglobulinemia E syndromes.[114–117] The extensive and unusual molluscum lesions observed in these patients include multiple papules and giant hyperkeratotic lesions. Keratoconjunctivitis can develop due to eyelid lesions.[116]

Laboratory Findings and Diagnosis

The diagnosis of molluscum usually is made clinically, but it can be confirmed by examination of smears of lesions for the presence of intracytoplasmic inclusion bodies.[109] Biopsy usually is not required. Molecular diagnostic assays have been developed,[118] but they are not used widely. Molluscum contagiosum is difficult to propagate in tissue culture. The presence of genital lesions in sexually active adolescents should prompt evaluation for other sexually transmitted infections.[110]

Treatment

Molluscum lesions usually resolve spontaneously within 6 to 18 months, and recurrences are rare. Intervention often is warranted for patients with underlying skin conditions or immunodeficiency.

Several topical treatments are available, including imiquimod, tretinoin, and cantharidin.[109,119,120] Therapeutic options are listed in Box 202.4. Molluscum lesions in patients with AIDS often spread despite aggressive therapy.[114] Topical cidofovir and other investigational treatments have been used in refractory cases.[109,121] Surgery may be required for removal of large, solitary lesions.

Box 202.4

Treatment Options for Molluscum Contagiosum

Physical Disruption

Curettage

Cryotherapy

Laser

Electrosurgery

Chemical Disruption

Cantharidin (topical)

Podophyllin (topical)

Trichloroacetic acid (topical)

Silver nitrate (topical)

Potassium hydroxide (topical)

Immune Modulation

Imiquimod (topical)

Tretinoin cream (topical)

Cimetidine (systemic)

Interferon α (intralesional)[a]

OK-432 (intralesional)[a]

Antiviral Therapy

Cidofovir (topical or systemic)[a]

Unknown

Taping or occlusion

---

[a] Investigational therapies reserved for severe cases.

Prevention

Isolation or exclusion of infected children from school or childcare settings is not warranted. The likelihood of transmission can be decreased by restricting sharing of towels and other potential fomites with infected persons. Genital lesions in adolescents should be treated to prevent sexual transmission.[122]

Acknowledgment

The author acknowledges inclusion of substantial material of Z.S. Moore from this chapter in the previous edition.

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of Poxvirus Infections

Epidemiology

- Smallpox has been eradicated as a human disease but concerns remain about its use as a potential weapon of bioterrorism.
- Vaccinia virus continues to be used as a vaccine and can cause disease in vaccinees and contacts of vaccinees.

- Infections due to zoonotic poxviruses (e.g., monkeypox, vaccinia, cowpox, parapoxviruses) usually occur sporadically in persons with animal exposure in enzootic areas.

- Molluscum contagiosum is a common infection worldwide, with the highest incidence among children younger than 5 years of age, those with atopic dermatitis, and those with certain immunodeficiencies.

Clinical Features

- Ordinary smallpox manifests as a febrile illness with characteristic development of a rash from macules to papules to vesicles to pustules in a centrifugal progression.

- Monkeypox is similar to smallpox clinically, but lymphadenopathy is more prominent in monkeypox and may help distinguish monkeypox from smallpox.

- Vaccinia, cowpox, and parapoxviruses usually cause self-limited, localized skin lesions, although more severe disease can occur in persons with immunocompromising or other medical conditions.

- Molluscum contagiosum manifests with multiple, small (1 to 5 mm), umbilicated papules that are pearly white or flesh colored.

Diagnosis

- Testing for poxviruses can include PCR, serology, electron microscopy, or other methods.

- Molluscum contagiosum usually is diagnosed clinically.

Treatment

- Vaccinia immune globulin (VIG) is licensed for the treatment of certain adverse events associated with vaccinia virus immunization.

- No antiviral drugs are licensed. Several investigational antiviral drugs show promise in treating orthopoxvirus infections in animal models.

- Development of orthopoxvirus antiviral therapeutics is an active area of research.

DNA Viruses: Herpesviridae

OUTLINE

203 Introduction to Herpesviridae
204 Herpes Simplex Virus
205 Varicella-Zoster Virus
206 Cytomegalovirus
207 Human Herpesviruses 6 and 7 (Roseola, Exanthem Subitum)
208 Epstein-Barr Virus (Mononucleosis and Lymphoproliferative Disorders)
209 Human Herpesvirus 8 (Kaposi Sarcoma–Associated Herpesvirus)

203

Introduction to Herpesviridae

David W. Kimberlin, Charles G. Prober

The family Herpesviridae contains three subfamilies: Alphaherpesvirinae, Betaherpesvirinae, and Gammaherpesvirinae.[1,2] The eight known human herpesviruses are represented in six genera, which are shown with the typical characteristics of the subfamilies in Table 203.1.

TABLE 203.1

Members of Herpesviridae Family

Subfamily	Characteristics	Genus	Member
Alphaherpesvirinae	Short reproductive cycle Efficient destruction of infected cells with release of viral progeny Rapid spread in culture Latency in sensory ganglia	*Simplexvirus*	Herpes simplex virus type 1 (human herpesvirus 1) Herpes simplex virus type 2 (human herpesvirus 2)
		Varicellovirus	Varicella-zoster virus (human herpesvirus 3)
Betaherpesvirinae	Long reproductive cycle Slow cell-to-cell spread in culture Enlargement of infected cells Multiple nonganglionic sites of latency	*Cytomegalovirus*	Cytomegalovirus (human herpesvirus 5)
		Roseolovirus	Human herpesvirus 6 Human herpesvirus 7
Gammaherpesvirinae	Replication in lymphoblastoid	*Lymphocryptovirus*	Epstein-Barr

	cells Latency in lymphoid tissue Monocytes and B lymphocytes		virus (human herpesvirus 4)
		Rhadinovirus	Human herpesvirus 8

All members of the Herpesviridae family share several features (Box 203.1), but the architecture of the virion best defines family membership. The typical herpes virion is roughly spherical and 150 to 200 nm in diameter. The virion consists of a core of linear, double-stranded DNA wrapped around a fibrillar core spool, an icosadeltahedral capsid containing 162 capsomeres; a layer of amorphous, asymmetrically distributed material surrounding the capsid called the tegument; and a lipid-containing outer envelope containing multiple embedded glycoprotein protrusions.

Box 203.1

Common Features of Members of Herpesviridae Family

General Features

- Viral particle size: 150–200 nm
- More than 30 structural proteins
- Icosahedral nucleocapsid with 162 capsomers, 100 nm in diameter
- Surrounded by an envelope, acquired by budding through the inner lamella of the nuclear envelope
- Multiple surface projections embedded in the envelope

DNA

- Linear double-stranded genome wrapped around a fibrillar spool core
- Contains terminal and internal reiterated sequences; variation in the number of reiterations among members
- Genomic size: 120–230 kb; size variation related to the number of sequence reiterations
- Specifies a large number of enzymes involved in nucleic acid

metabolism

Features of Replication and Persistence

- Complex replication occurs in the nucleus
- Destruction of an infected cell accompanies production of progeny
- Latency follows primary infection, with lifetime persistence of viral DNA in infected hosts
- Potential for clinically apparent (symptomatic) or clinically inapparent (asymptomatic) reactivation throughout the life of the host

The most important biologic property of members of the Herpesviridae family is their ability to establish a latent state marked by persistence in an infected host after primary infection for the remainder of the host's lifetime. The different sites of latency are a distinguishing feature of the three Herpesviridae subfamilies (see Table 203.1). The viral genome takes the form of closed circular molecules within latently infected cells, but with reactivation, the genome again becomes linear. Clinical correlation of this biologic cycle is virus specific and is observed through a lifelong risk of viral reactivation, with or without recrudescence of symptoms.

Primary infection generally results in more severe symptoms than reactivated infection. However, mild or subclinical primary infection can be followed by more severe reactivated infection. The initial viral exposure results in primary infection, which can lead disease (i.e., clinically apparent symptoms and signs of the infection) or can be an asymptomatic infection. Reactivation of herpesviruses from a latent form also can be an asymptomatic infection, during which viral replication is occurring and transmission is possible, or can be symptomatic disease, with clinically apparent symptoms and signs due to viral replication and with the possibility of viral transmission. This concept of *active infection*, *latent infection*, and *clinically apparent disease* is critical to the appropriate interpretation of diagnostic tests and to the rationale of different treatment strategies in immunocompetent and immunocompromised hosts.

Herpes Simplex Virus

David W. Kimberlin, Charles G. Prober

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) belong to the Alphaherpesvirinae subfamily of herpesviruses.[1] The large DNA viruses have a short reproductive cycle, rapidly produce lytic infection in tissue culture, and remain latent in sensory neural ganglia. After infection of the oral mucosa, usually by HSV-1, the virus becomes latent in the trigeminal ganglia. After genital infection by HSV-2 or HSV-1, the latent virus remains in the sacral ganglia.

In common with other herpesviruses, the HSV core of linear, double-stranded DNA is contained within an icosahedral capsid that consists of 162 capsomeres. The capsid is surrounded by a tightly adherent membrane of tegument protein and a phospholipid-rich envelope. The complete virion has an approximate diameter of 110 to 120 nm. Complete DNA sequencing demonstrates a greater than 90% homology between HSV-1 and HSV-2.

The HSV genome encodes at least 84 different polypeptides. They include glycoproteins embedded in the viral envelope; capsid proteins; DNA polymerase, protein kinase, and other viral enzymes; DNA-binding proteins involved in viral replication; and many other proteins with poorly understood biologic functions.[2] Attachment of HSV to cell surface receptors initiates infection. After attachment, the HSV envelope fuses to the plasma membrane, allowing the viral capsid to be transported to the nucleus, where the viral DNA is released. Transcription, DNA synthesis, capsid assembly, DNA packaging, envelopment, and release of new viral progeny ensue in infected cells.[2]

Several viral surface glycoproteins are important determinants of virulence. For example, glycoprotein B (gB) and gC mediate cellular attachment, gD is required for viral entry into cells, and gE is required for efficient expression of late genes, and with gI, it forms a potent Fc receptor.[2]

The first set of viral gene products to be synthesized includes the six immediate early (IE) proteins; five of the IE proteins regulate the reproductive cycle of the virus, and one blocks the presentation of antigenic peptides on the cell surface. The second set of proteins produced comprises the early proteins. These proteins, which include thymidine kinase and DNA polymerase, primarily are responsible for viral nucleic acid synthesis and are the main targets of the antiviral therapeutic drugs. The third set of proteins, known as late proteins, assembles to form the capsid and tegument. These proteins ultimately facilitate viral envelopment.

Pathophysiology

Infection of the susceptible host occurs when virus penetrates through abraded skin or mucosal surfaces. It is hypothesized that HSV enters cutaneous neurons after minimal replication at the site of inoculation and then migrates along innervating axons to the sensory ganglia, where infectious virus is produced.[3] Visible lesions result when virus subsequently travels back to the inoculation site through peripheral sensory nerves, replicates, and destroys epithelial cells.[4] Histology of skin lesions shows sequential changes of balloon degeneration of infected cells, with condensation of nuclear chromatin, degeneration of cell nuclei and plasma membranes, and formation of multinucleated giant cells. Initially, vesicular lesions appear between epidermal and dermal layers and contain large amounts of virus, cell debris, and inflammatory cells. As additional inflammatory cells are recruited, pustular lesions replace vesicles, and healing ensues. Mucosal membrane lesions are more ulcerative than skin lesions, because the thin layer of epithelium in mucosal lesions ruptures readily. Histologic changes observed in primary infection usually are more severe than those of recurrent episodes.

Occasionally, spread occurs beyond the dorsal root ganglia or the localized mucocutaneous eruption, leading to generalized infection. When the host is unable to contain viral replication, viremia can result in multiorgan involvement. Disseminated clinical infection occurs most often in neonates and patients with compromised immune systems, including pregnant women, but it also occurs rarely in immunocompetent hosts.

Establishment of lifelong latency, interrupted by periods of recrudescence, is an important feature of HSV infections. Maintenance of the latent state probably depends on several factors, including the number of neurons infected during the primary episode, the number involved with each reactivation, and the possible incremental involvement of additional neurons with each recurrent episode.[5] During latency, the HSV genome is maintained in a repressed, noninfectious, static state. Transcriptional latency patterns of HSV-1 and HSV-2 are similar.[6] The molecular basis of latency and reactivation involves the active expression of only a single diploid gene encoding latency-associated transcripts.[7] Maintenance of the virus in this nonreplicating state does not compromise the survival and normal function of host ganglion cells.

Periodic reactivation of HSV and centrifugal spread down the neural axon are associated with the development of recurrent lesions (i.e., clinically apparent disease) or asymptomatic viral excretion (i.e., asymptomatic infection). Several stimuli can precipitate reactivation from a latent state, including manipulation of nerve roots, direct trauma to ganglia or the skin or mucosa innervated by peripheral nerves, exposure to ultraviolet light, stress, hormonal changes such as those accompanying menses, administration of immunosuppressive agents, and illness from another cause.

The likelihood of viral reactivation is related to virus type and the interaction between the virus and the host's immunologic systems. Viral reactivation from latency is common after primary orolabial infection with HSV-1 and after genital infection with HSV-2. In contrast, when primary orolabial infection is caused by HSV-2 or primary genital infection is caused by HSV-1, recurrences are less common, reflecting the adaptation achieved by these two viruses for their usually preferred areas of the body. For example, less than 25% of people have recurrences after first-episode infections of the genital tract caused by HSV-1, whereas more than 60% have recurrences after genital HSV-2 infections.[7,8] The likelihood that recurrences are associated with symptoms depends on the quantity of reactivated virus, virus-cell interactions, and host immune factors.

Immunity

The immune response to HSV is initiated as a containment strategy and continues as a curative strategy.[9] The usual result in normal hosts is the localization of virus to a limited anatomic area with neutralization of infectivity, followed by establishment of latency. Despite extensive investigation, specific immunologic factors that modulate the clinical course and outcome of HSV infections remain incompletely understood. Although HSV infections tend to be more severe in patients with cellular rather than humoral immunodeficiencies, both antibody- and cell-mediated responses are important in influencing the acquisition of disease, the severity of infection, and the frequency of recurrences.[10]

The important role of antibody in HSV infections is evident from investigations of neonates exposed to HSV at the time of delivery. Those exposed to HSV-2 in the presence of transplacentally acquired neutralizing antibody are significantly less likely to contract infection[11] and, if infected, usually have localized disease manifesting later in the neonatal period.[12] Titers of antibodies that mediate antibody-dependent cellular cytotoxicity (ADCC) correlate inversely with severity of neonatal infection.[13]

Humoral immunity also seems to be relevant to the pathogenesis of HSV infections beyond the neonatal period. For example, HSV-1 seropositive stem cell transplant recipients who have HSV-1 seropositive donors have shorter and less frequent episodes of HSV-1 infection than do those who have HSV-1 seronegative donors.[14] Low levels of mononuclear cell ADCC activity in patients with leukemia correlate with greater susceptibility to HSV infections.[15] Antibodies against HSV-1 provide partial protection against HSV-2 infection. Prior HSV-1 infection reduces the risk of contracting HSV-2 infection by about 50%,[16] and a first episode of genital infection caused by HSV-2 is less severe if people have preexisting HSV-1 antibodies.[17] Investigations focused on local defense mechanisms have identified the protein targets of antibodies to HSV and their appearance in mucosal secretions.[18] These studies underscore the role of humoral immune response in HSV infections.

It is well established that the cellular immune response is critical for the control of HSV infections, but which HSV antigens are the most important inducers of protective responses remains unknown. Substantially diminished HSV antigen-stimulated lymphocyte proliferation and reduced interferon production are observed in infected neonates and postpartum women compared with responses in nonparturient adults.[19]

Epidemiology

Most infections caused by HSV are asymptomatic or nonspecific. Defining the epidemiology of HSV has depended on seroepidemiologic studies, which initially were confounded by extensive antigenic similarities between HSV-1 and HSV-2. The development over the past 2 decades of commercially available, type-specific assays for antibodies unique to HSV-1 and HSV-2 has provided a means of reliably determining prior infection with each virus.[20]

Beyond the neonatal period, primary infection with HSV-1 usually occurs in infancy or childhood, whereas primary infection with HSV-2 occurs after the onset of sexual activity. HSV infections occur throughout the world, with humans serving as the only reservoir. Acquisition of virus follows intimate mucocutaneous contact between a susceptible host and a person who is shedding virus during primary infection or reactivation. Because HSV infection results in lifelong latency, the prevalence in any population is cumulative. Because transmission and acquisition of virus usually occur in the absence of symptoms, the spread of infection throughout a population can be silent. These factors account for worldwide endemic HSV infection.

Infections caused by HSV have no seasonal predilection, but geographic location, socioeconomic status, age, and race influence the prevalence of infection in most studies.[3] Data from the United States and other industrialized countries document a decline in HSV-1 seroprevalence among adolescents over the past 1 to 2 decades due to improvements in living conditions, better hygiene, and less crowding.[21–25] Despite these declines, HSV-1 infection remains more common among non-Hispanic US blacks and Mexican Americans than among non-Hispanic US whites and among respondents with lower than higher incomes.[26,27] Approximately one third of children from lower socioeconomic populations and 20% from middle-income populations have serologic evidence of HSV infection by 5 years of age. Prevalence rises in lower socioeconomic populations to more than three fourths by adolescence, although not in middle-income populations until the second or third decade of life.

Beginning in the mid-1960s, population-based studies of genital herpes revealed a rising incidence of clinically evident genital disease, with most first infections occurring in those 18 to 36 years of age.[28] Estimating the prevalence of HSV-2 infection on the basis of clinically apparent genital disease has major limitations of misclassifying HSV-1 genital infections[29–32] and missing most HSV-2 infections, which are inapparent.[33]

Population-based serosurvey studies, which have used type-specific assays that reliably detect antibodies to HSV-2, demonstrated an increase of more than 30% in the prevalence of HSV-2 infections between the late 1970s and the early 1990s.[34] Subsequently, HSV-2 seroprevalence in the United States has decreased, and the current seroprevalence of HSV-2 among young adults is 10% to 20%.[22] Age, race, sex, and history of other sexually transmitted infections (STIs) affect seroprevalence rates. HSV-2 infection rates are comparatively higher among blacks, women, and persons attending STI clinics.[34] Seroprevalence of HSV-2 among pregnant women has ranged consistently from 15% to 30%.[35]

Transmission of HSV-2 typically results from contact with an asymptomatic sexual partner. In one study evaluating contacts of 66 people who had genital herpes, only one third of source partners reported recent genital herpetic lesions, one third described genital symptoms that were atypical of genital herpes, and one third had no prior symptoms.[36] In another prospective study evaluating 144 heterosexual partners in whom one partner was seronegative and the other had symptomatic, recurrent genital HSV, 70% of all transmissions resulted from contact during periods of asymptomatic viral shedding.[37] The reported risk of acquisition of infection in these cohorts is approximately 10% per year.[37,38]

Clinical Syndromes

Orolabial Infection

Primary Infection

Most HSV infections occurring above the waist are caused by HSV-1 and are localized to the mouth and oropharynx (Fig. 204.1). Limited data suggest that only about 10% to 30% of cases of perioral HSV infections in children are associated with signs and symptoms of illness.[39,40] The classic clinical presentation of primary herpetic gingivostomatitis as extensive orolabial HSV lesions with primary HSV infection in the young child is an unusual manifestation.

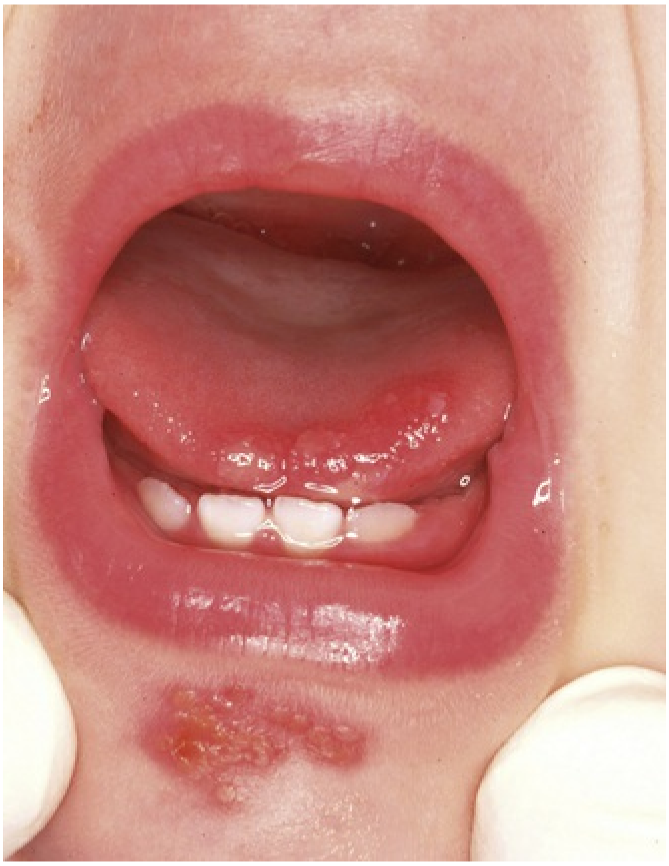

FIGURE 204.1 Toddler with 3 days of high fever and poor intake has typical herpes simplex virus

vesicoulcerative lesions on the tongue and cluster of vesiculobullous lesions below the lip. (Courtesy of J.H. Brien ©.)

When symptomatic disease occurs, high fever, irritability, tender submandibular lymphadenopathy, and mucocutaneous eruption evolve after a mean incubation period of 3 to 4 days. Detection of HSV DNA in the blood by polymerase chain reaction (PCR) occurs in about one third of symptomatic children.[41] Vesiculoulcerative lesions can involve the palate, gingiva, tongue, lip, and facial area.[42,43] Intraoral edema and pain are associated with lesions that evolve from vesicles to shallow ulcers on an erythematous base. The most common reason for hospital admission with primary gingivostomatitis is dehydration resulting from impaired eating and drinking. The duration of symptoms in primary gingivostomatitis ranges from 2 to 3 weeks.

Pharyngitis is a common manifestation of primary HSV infection in older children and adults. HSV has been isolated from the posterior pharynx of 5% to 24% of college students with pharyngeal symptoms.[44,45] HSV pharyngitis cannot be distinguished clinically from other viral and bacterial infections. Common manifestations of illness are pharyngeal erythema, exudative or ulcerative lesions on the posterior pharynx and tonsils, enlarged cervical lymph nodes, and fever.[44,45]

Reactivation of Infection

Reactivation of HSV from the trigeminal ganglia usually is not associated with clinical findings. It is estimated that silent excretion of virus in healthy, previously infected people occurs on about 1% of days for children and 5% to 10% of days for adults.[46] Reactivation of infection commonly follows manipulation of the trigeminal nerve route,[47] dental procedures,[48] or stimuli such as fever, ultraviolet radiation, or exposure to the sun.[49,50] The frequency of recurrences varies, but on average, approximately one third of people with prior infection have clinically evident recurrences.[51]

Signs and symptoms associated with clinical recurrences usually are mild.[52] Many patients have prodromal symptoms of pain, burning, or tingling that precede the eruption by 1 to 2 days. The most common site of recurrent orolabial lesions is the outer edge of the vermilion border. On average, three to five lesions are seen.

Lesions begin as vesicles, evolve into pustules or ulcers in 1 to 2 days, and heal completely within 8 to 10 days. Pain is greatest at the onset of eruption and resolves within 4 to 5 days. Unilateral clusters of lesions can occur on skin along trigeminal nerve distribution, with or without conjunctivitis (see Fig. 82.1 in Chapter 82). Viral excretion and infectivity last only 2 to 3 days; the titer of virus varies from less than 10 plaque-forming units (PFUs)/mL in the prodromal phase to almost 10^5 PFUs/mL in the vesicular phase.

Genital Infection

Familiarity with the serologic classification of genital herpes infection is important for understanding of the biologic and clinical features of the disease.[53] When a person with no prior HSV-1 or HSV-2 antibody acquires either virus in the genital tract, a *first-episode primary infection* results. If a person with preexisting HSV-1 antibody acquires HSV-2 genital infection, a *first-episode nonprimary infection* ensues. Viral reactivation from latency and subsequent antegrade translocation of virus to skin and mucosal surfaces produces a *recurrent infection*, which presupposes preexisting homologous antibody to the reactivating HSV.

Historically, most first-episode genital herpes infections were caused by HSV-2. However, an increasing proportion, especially among young adults, is caused by HSV-1.[29–32] Whereas only 5% to 10% of adults in the United States have a history suggesting prior genital herpes infection, seroepidemiologic studies show that approximately one in five people 30 to 39 years of age and one in four persons 40 to 49 years of age have been infected with HSV-2.[22] Seroprevalence rates exceed 40% among attendees of US STI clinics, with comparatively higher rates for women and blacks.[54]

First-Episode Primary Infection

About 40% of men and 70% of women seeking medical care for primary genital herpes have constitutional symptoms. Headache, fever, myalgia, and backache develop after a mean incubation period of 7 days. Symptoms peak within 4 days of onset of lesions and gradually abate over 7 to 10 days. Local symptoms such as itching and pain usually precede visible lesions by 1 to 2 days. New lesions appear over 7 to 8 days. Lesions evolve from vesicles and pustules to wet ulcers over approximately 10 days and then crust and heal during the ensuing 10 days.

Lesions are distributed over the labia majora, labia minora, mons pubis, vaginal mucosa, and cervix in women. In men, lesions typically occur over the shaft of the penis. About 85% of women have vaginal discharge, and 25% of men have urethral discharge. More than 80% of women and more than 40% of men have dysuria for 7 to 10 days. Tender inguinal lymphadenopathy typically appears during the second or third week of illness in about 80% of both sexes and usually is the last sign to resolve. Mean duration of viral shedding is 11 days.

Extragenital complications of primary HSV infections include aseptic meningitis, mucocutaneous lesions beyond the genital area, pharyngitis, and visceral dissemination. These complications are more common in women than in men.[17]

First-Episode Nonprimary Infection

Almost one half of people with their first clinical outbreak of genital herpes have preexisting antibodies to the heterologous herpes virus. Presumably as a result of the preexisting immunity to shared HSV antigens, these people have lower frequencies of systemic symptoms and extragenital complications, fewer lesions, shorter duration of pain, and more rapid healing than patients with primary infections.[17]

Recurrent Infection

Most recurrences of genital herpes are asymptomatic. About 1% of people previously infected with HSV-2 have active viral shedding without symptoms on any given day.[55] Shedding of HSV from the genital tract occurs in people seropositive for HSV-2, even if they have no prior history of genital herpes.[56] Average duration of episodes of asymptomatic viral shedding is 1.5 days, but it can be as short as a few hours.[57] Recurrent clinical genital herpes usually is mild, with constitutional symptoms in only 5% of men and 10% of women. Of those who have symptoms, more than 40% of women and more than 50% of men have local prodromal symptoms for several hours to 3 days.[17] Genital lesions, which usually are few and confined, typically increase in size over the first 3 days, reach a plateau at 6 days, and resolve rapidly. Mean time to complete healing is 9 to 10 days, and duration of viral shedding is 4 days. Tender lymphadenopathy, dysuria, vaginal discharge, and systemic complications occur less commonly.

Factors implicated in precipitating recurrences include emotional stress, menses, and sexual intercourse. Genital shedding of HSV-2 in women as determined by PCR is increased in the setting of hormonal use, bacterial vaginosis, and high-density vaginal colonization with group B *Streptococcus*.[58]

Keratoconjunctivitis

Ocular herpes infection beyond the neonatal period usually is caused by HSV-1. Approximately 300,000 cases of HSV infection of the eyes are diagnosed each year in the United States.[3] Infection involves one or both eyes, with a typical course of follicular conjunctivitis associated with pain, photophobia, and tearing and followed by chemosis, periorbital edema, and preauricular lymphadenopathy.[59] Periocular skin involvement can occur.

As infection progresses, diffuse punctate lesions occur on the cornea, followed within days by the appearance of serpiginous ulcers. Pathognomonic branching dendritic lesions (see Figs. 82.1, 82.2, and 82.3 in Chapter 82) of the cornea appear and are associated with blurred vision. Deeper stromal structures can be injured, especially after injudicious use of topical corticosteroids. Healing can require more than 1 month.

After primary ocular HSV infection, recurrences are observed in about one third of people during the ensuing 5 years. Recurrences can include reappearance of dendritic ulcerations or deep stromal injury that can threaten sight.

Cutaneous Infections

HSV can infect skin outside the perioral and genital areas. Infection of the pulp or nail bed of the finger is a typical site and is referred to as *herpetic whitlow*. Whitlow is most common in medical and dental professionals, in whom it results from digital contamination with genital and oral secretions, respectively.[60,61] Young children have herpetic whitlow as a result of autoinoculation of HSV-1 during primary oral herpes infection or when an infected adult inoculates the virus while trimming the child's nails by biting them[62] (Fig. 204.2). In adolescents and adults, herpetic whitlow usually follows autoinoculation from genital secretions during first-episode HSV-2 infection.[63]

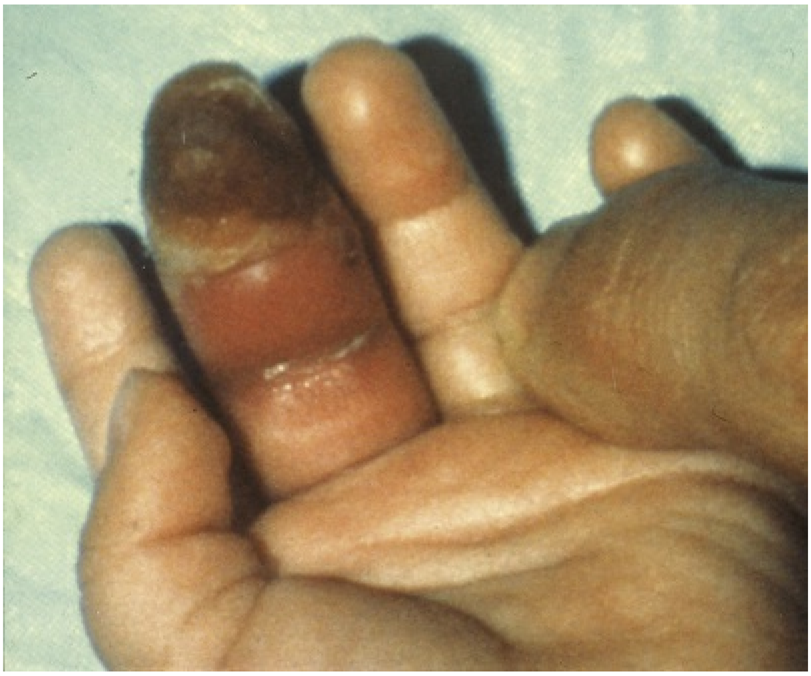

FIGURE 204.2 Herpetic whitlow due to herpes simplex virus type 1 (HSV-1) in an infant whose mother trimmed his nails with her teeth. (Courtesy of S.S. Long.)

Discrete vesicular or pustular lesions arise over the distal phalanx and coalesce over several days, frequently appearing purplish and dusky. Infection is associated with local tingling, burning pain, erythema, and edema, and it can be accompanied by fever, lymphangitis, and tender swelling of related lymph nodes. Lesions often are confused with bacterial cellulitis. Surgical intervention is contraindicated. Crusting of the lesions occurs after about 10 days and is followed by healing and reappearance of normal skin. Lesions recur but at rates lower than those observed with oral or genital disease.

HSV-1 causes cutaneous infection among athletes participating in contact sports, such as wrestling and rugby, referred to as *herpes gladiatorum* and *scrum-pox,* respectively.[64,65] Viral inoculation results from close contact between oral secretions and abraded skin.[66]

Surveys of athletic trainers suggest that this infection is endemic among young competitive wrestlers.[67] In the largest outbreak of herpes gladiatorum reported, infection was diagnosed in 60 high school wrestlers[68]; 73% of infected wrestlers had lesions on the head, 42% on the extremities, and 28% on the trunk. About 25% of the infected boys had fever, chills, and headache, and 40% had sore throat.

Herpes infections of skin damaged by diaper dermatitis, thermal burns, or atopic dermatitis/eczema (i.e., eczema herpeticum) can be particularly severe.[69–71] Rapidly spreading eruptions and visceral dissemination can occur.

HSV is the most commonly recognized precipitating factor for recurrent erythema multiforme and is identified as the precipitant in about one fourth of cases.[72] In one study, HSV type-common glycoprotein antigen (i.e., crude antigen) was found in 12 of 16 skin biopsy specimens of erythema multiforme lesions.[73]

Central Nervous System Infections

HSV causes a variety of central nervous system (CNS) illnesses during and after infection. Self-limited aseptic meningitis occurs after first-episode genital infection. HSV is the most common cause of sporadic fatal encephalitis, accounting for approximately 10% to 20% of viral encephalitis cases in developed countries.[74,75] Beyond the neonatal period, HSV encephalitis typically is caused by HSV-1.

Encephalitis has a biphasic age predilection, with about one third of cases occurring in people younger than 20 years of age and approximately one half of cases occurring in people older than 50 years of age. Encephalitis can occur as a result of primary (~25%–33% of cases) or recurrent infection (~67%–75% of cases).[76–78] Typically, patients have fever, altered consciousness, unusual behavior, and focal neurologic abnormalities, with signs and symptoms consistent with temporal lobe involvement. Although antiviral therapy has resulted in a dramatic decrease in mortality rates, a substantial number of survivors are left with various degrees of neurologic impairment, including cognitive deficits, behavioral disorders, and recurrent seizures.

Patients with HSV encephalitis may have an increased number of red blood cells in cerebrospinal fluid (CSF); counts greater than1000/mm^3 are common, and counts greater than 25,000/mm^3 have been observed.[70] This “hemorrhagic encephalitis” historically suggested HSV encephalitis and was related to HSV's propensity to cause damage across tissue planes, including across blood vessel walls. With earlier diagnosis of HSV encephalitis due to heightened awareness and improved diagnostic testing, CSF red blood cells are seen less often than in the 1970s and 1980s.

The CSF usually has a few hundred white blood cells (WBCs)/mm^3, with a predominance of lymphoid cells (75% to 100%). However, pleocytosis varies from a few to more than 1000 WBCs/mm^3, and occasionally neutrophils predominate; 10% to 20% of CSF specimens can be acellular, especially if obtained early in the disease.[79] Protein concentration is normal in about one half of CSF specimens obtained during the first week of illness, but thereafter, concentrations as high as 500 to 1200 mg/dL are observed.[79]

Production of HSV-specific antibody in the CNS occurs by the second week of illness, resulting in an increased ratio of CSF-to-serum concentration of HSV antibody.[79] Virus can be isolated from culture of CSF in approximately 4% of cases.[77] The finding of HSV DNA in CSF, identified by PCR testing, is sensitive and specific for the diagnosis of HSV encephalitis[80] and has revolutionized confirmation of infection by eliminating the need for brain biopsy. However, CSF obtained before the third day of illness can be falsely negative by PCR.[81,82] If the index of suspicion remains high for HSV encephalitis, a repeat lumbar puncture for CSF analysis by PCR should be performed.

Electroencephalography typically reveals focal spike and slow-wave abnormalities early in the course of HSV encephalitis. A characteristic finding is paroxysmal lateralizing epileptiform discharges (PLEDs). Neurodiagnostic images can be normal at the onset of infection, followed within days by development of edema associated with focal infection or hemorrhagic necrosis. Magnetic resonance imaging is a more sensitive early test than computed tomography (Fig. 204.3).[83]

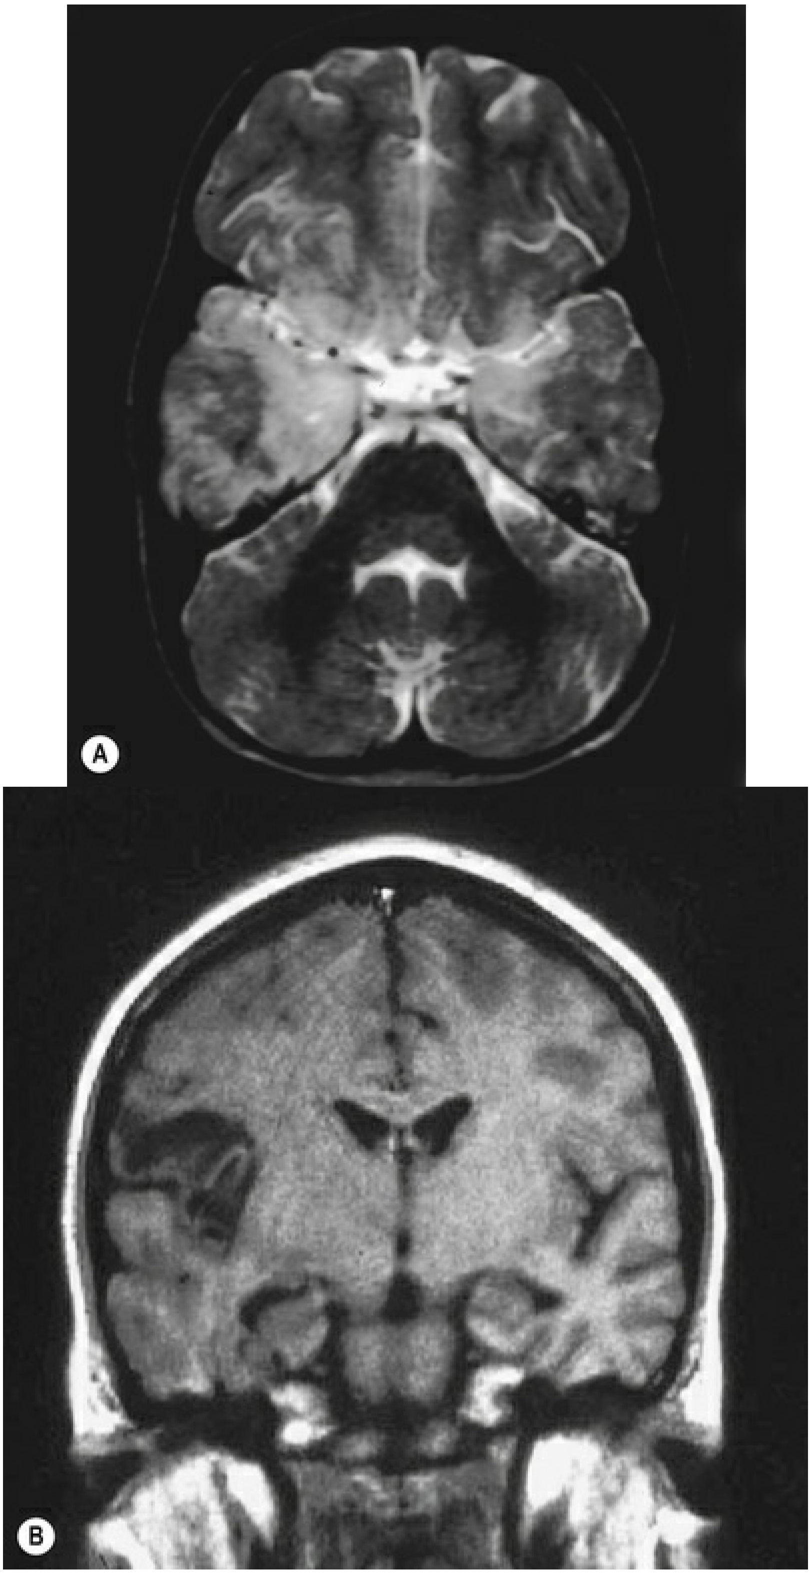

FIGURE 204.3 (A) Axial T2-weighted magnetic resonance imaging (MRI) of a 27-day-old infant with herpes simplex virus type 2 (HSV-2) encephalitis. The image shows edema with necrosis of the temporal lobes bilaterally, with less involvement of parietal lobes. The mother had only a distant history of genital HSV more than 15 years before this pregnancy and no

clinical recurrence within recent years. (B) Coronal T1-weighted MRI of a 13-year-old adolescent with acute onset of left-sided seizures due to HSV-1 encephalitis. Notice the right-sided temporal lobe necrosis and edema. (A, Courtesy of S.S. Long. B, Courtesy of J.H. Brien ©.)

Several unusual CNS manifestations attributed to HSV have been described. They include recurrent aseptic meningitis (i.e., Mollaret meningitis), brainstem encephalitis, ascending myelitis, parainfectious encephalomyelitis (i.e., acute disseminated encephalomyelitis), and encephalomyeloradiculitis.[84] HSV has been implicated in the pathogenesis of several other neurologic syndromes, including Bell palsy, atypical pain syndromes, trigeminal neuralgia, vestibular neuritis, and temporal lobe epilepsy.

Other Infections

Unusual clinical manifestations of HSV have been described in immunocompetent hosts. They include visceral dissemination, esophagitis, tracheobronchitis, pneumonitis, and hepatitis. Viremia with visceral dissemination can result in infection of any organ. Beyond the neonatal period, disseminated infection is more common in adults, especially pregnant women, than in children.

Isolated esophageal involvement has been described in some patients, with a mean age of 35 years.[85] Most infections were caused by HSV-1, and most were primary. Symptoms suggesting esophageal HSV include retrosternal chest pain and odynophagia.

Necrotizing and exudative tracheobronchitis due to HSV can precipitate bronchospasm, often necessitating mechanical ventilation. Most reported cases have involved elderly adults or immunocompromised hosts.[86] HSV pneumonitis can result from spread down the tracheobronchial tree, extension from esophageal involvement, or hematogenous dissemination.

Hepatic infection caused by HSV rarely occurs in normal hosts but rather affects neonates, pregnant women, and persons with underlying conditions.[87] Infection usually is fulminant in nature, with death commonly ensuing as a result of severe hepatic necrosis and consequent uncontrolled liver failure and coagulopathy.

Acute retinal necrosis can occur as a reactivation-immunologic event. It has been reported as long as 9 years after a perinatally acquired infection.[88]

Intrauterine and Perinatal Infections

Congenital (in utero) infection due to intrauterine exposure to HSV is rare.[89–91] Manifestations of congenital infection usually include the triad of cutaneous manifestations (e.g., active skin lesions, scarring from old lesions), ocular involvement (e.g., chorioretinitis, microphthalmia), and CNS abnormalities (e.g., microcephaly, hydranencephaly). Hydrops fetalis has been reported as a rare manifestation.[92] Neonates with in utero HSV infection have disease manifestations apparent within the first 24 to 48 hours of life (Fig. 204.4).

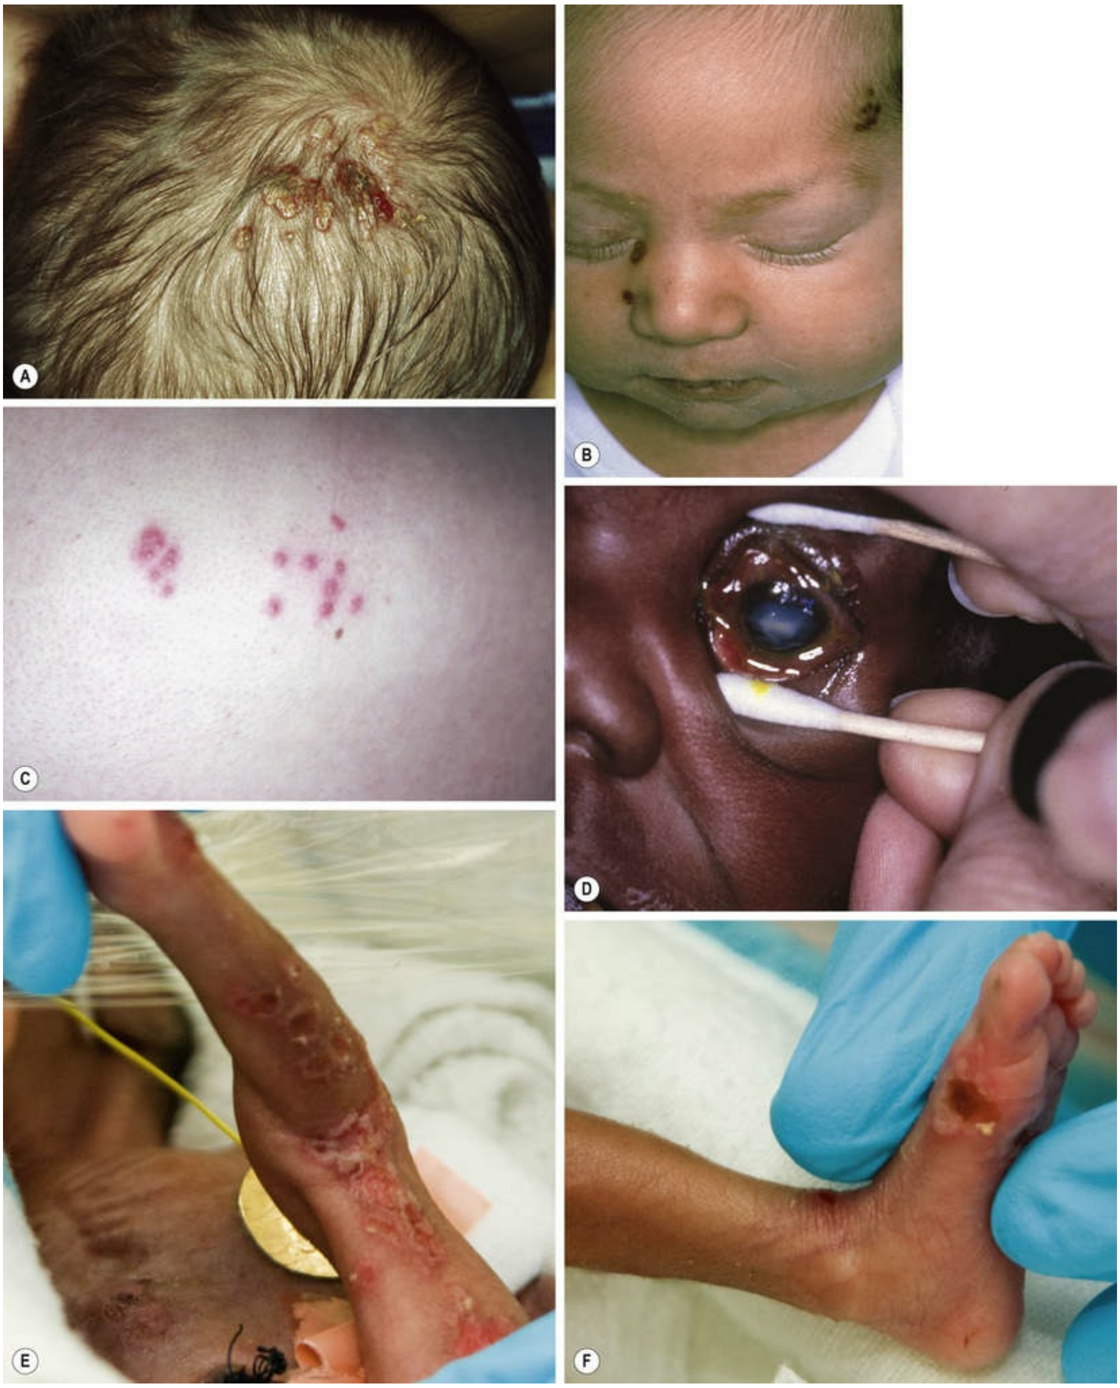

FIGURE 204.4 Mucocutaneous manifestations of herpes simplex virus (HSV) in the neonate. (A and B) Clusters of vesicular lesions are seen at the scalp electrode site and on the face of an infant. (C) Early skin vesicles are seen in another infant. (D) An infant was discharged from the nursery at 2 days of age with the diagnosis of chemical conjunctivitis. He returned at 8 days of age with keratoconjunctivitis. HSV-2 was isolated from the conjunctiva. (E and F) Infant who was born at 25 weeks' gestation and 72 hours after rupture of the membranes (i.e., footling presentation) had

onset of raised vesiculobullous lesions on day 4 of life, with rapid spread down the leg and ulceration. HSV-2 was recovered from mucocutaneous sites, and polymerase chain reaction (PCR) testing was positive for blood and cerebrospinal fluid samples. (A, B, and C, Courtesy of J.H. Brien ©. D, Courtesy of S.S. Long. E and F, Courtesy of S.G. Pinniti, K.N. Feja, M. Hiatt, and R.W. Tolan, Jr., The Children's Hospital at Saint Peter's University Hospital, New Brunswick, NJ.)

Most neonatal HSV infections are perinatally acquired; they result from exposure to virus in the maternal genital tract at delivery.[93] The risk of neonatal infection is largely influenced by the HSV antibody status of the mother. About 50% to 60% of neonates exposed to maternal primary infection acquire HSV infection, whereas infection occurs in approximately 2% of those exposed to recurrent infection at delivery.[11,94]

In neonates, HSV infection manifests in three ways (Table 204.1). Signs of neonatal infection are invariably evident by 4 to 6 weeks of age, and illness with onset after this time is unlikely to be caused by perinatally acquired HSV. Approximately 25% of neonatal HSV infections involve visceral organs (e.g., liver, lungs, bone marrow) with or without brain involvement (i.e., disseminated disease), whereas the other two manifestations by definition do not have dissemination. They are brain involvement with or without skin lesions (i.e., CNS disease), occurring in approximately 30% of neonatal HSV cases, and infection limited to the skin, eyes, and mouth (i.e., SEM disease), occurring in approximately 45% of cases.[95]

TABLE 204.1

Characteristics of Neonatal Herpes Simplex Virus Infections

Feature	Skin, Eye, and Mucous Membrane Infection	Central Nervous System Infection	Disseminated Infection
Usual age at onset	7–14 days	14–21 days	5–12 days
Clinical findings	Vesicles on an erythematous base; conjunctivitis	Lethargy, irritability, fever, seizures	Shock, hepatomegaly, jaundice, bleeding, respiratory distress
Diagnostic testing	Culture of skin lesions, with or	Culture of skin lesions, if present, with or without PCR; DFA of	Cultures of skin lesions, if present, with or without PCR;

	without PCR; DFA of skin lesions	skin lesions; indices and PCR on CSF; EEG; neuroimaging studies	DFA of skin lesions; culture of nasopharynx, axillae, rectum
Mortality rate if treated	0%	5%	30%
Sequelae rate if treated	0%	30%	15%

CSF, cerebrospinal fluid; DFA, direct fluorescent antibody test; EEG, electroencephalogram; PCR, polymerase chain reaction.

SEM disease (see Fig. 204.4) typically manifests during the first 2 weeks of life. Skin lesions tend to appear at sites of trauma, such as the site of attachment of fetal scalp electrodes, the bulb syringe trauma site on palatal mucosa, the margin of the eyes, or at a circumcision site or over the presenting body part. Lesions evolve rapidly from macules to vesicles on an erythematous base. HSV infection should be considered whenever any vesicle appears on a neonate. The outcome of SEM disease is excellent if the diagnosis is made promptly and antiviral therapy is initiated. When the disease is not treated, about 80% of cases progress to disseminated or CNS disease.[95,96]

HSV infection of the CNS tends to manifest slightly later in the neonatal period than other categories of neonatal HSV infection. Typically, fever and lethargy appear between 2 and 3 weeks of age, followed by the onset of seizures, which can be focal and difficult to control; skin lesions exist in about 35% to 40% of cases at the time of presentation. Some infants who come to medical attention quickly have only nonspecific signs and symptoms. In 8 of 8 cases, patients were younger than 14 days of age in one retrospective study,[97] and 15 of 16 were younger than 21 days of age in another.[98]

CSF examination usually reveals a mild pleocytosis (50–400 WBCs/mm^3, predominantly mononuclear), a slightly reduced glucose level, and a modestly to markedly elevated protein concentration (500–1000 mg/dL). The electroencephalogram typically is abnormal diffusely. Computed tomography can be normal early in the course of CNS disease; magnetic resonance imaging is a more sensitive study. Temporal lobe involvement is typical, but diffuse infection can occur. Without therapy, one half of neonates with CNS HSV infection die, and most survivors sustain severe neurologic impairment.[99]

Disseminated neonatal HSV infection often mimics severe bacterial infection, with onset typically occurring during the first 2 weeks of life. Common clinical findings include cardiovascular instability, hepatomegaly, jaundice, bleeding, and respiratory dysfunction. Almost 60% of patients have skin lesions at some time during their illness, but lesions often are absent at the onset of symptoms. Progression of infection is rapid, with death caused by unremitting shock, progressive liver failure, bleeding, respiratory failure, or neurologic deterioration.[96]

Infection in Compromised Hosts

HSV infection in immunocompromised hosts is a frequent source of morbidity but is uncommonly fatal. Risk of severe HSV parallels the extent of compromise of cellular immune responses. The most frequent complication of HSV infections among these patients is severe ulcerations that develop on keratinized and nonkeratinized mucosal surfaces.[100] Oral and genital lesions progress slowly, with accompanying tissue damage and necrosis. Healing takes an average of 6 weeks. Local cutaneous dissemination can occur. Contiguous mucosal spread of infection can result in esophageal, tracheal, or pulmonary involvement or in visceral dissemination.[101]

Laboratory Findings and Diagnostic Techniques

Identification of Virus

Culture.

Culture is the most specific method for diagnosing an active HSV infection. Samples from skin lesions should be obtained by aspiration of the contents of intact skin lesions, swabbing of the bases of denuded skin lesions, or swabbing of the mucosal sites of prior outbreaks. Premoistened cotton swabs are preferred for collection of specimens for culture because calcium alginate–impregnated swabs inhibit virus isolation.[102] If direct inoculation onto culture media at the time of collection is not feasible, specimens should be placed into 1 to 2 mL of medium for viral transport. Specimens transported to reference laboratories at room temperature within 3 days yield adequate recovery of HSV.[103] For prolonged storage, specimens should be maintained at −70°C. Freezing at −20°C before processing and multiple cycles of freezing and thawing reduce the viability of HSV.

The typical cytopathic effect of HSV in vitro is foci of enlarged, refractile cells in the monolayer of a variety of cell culture lines. The time required to observe a cytopathic effect after incubation depends on the concentration of virus in the sample; a cytopathic effect is evident within 24 hours if the sample contains high concentrations of virus and within 4 to 5 days if there is a low concentration. Timing of specimen collection is critical; HSV can be recovered from more than 90% of genital herpes lesions sampled during the vesicular stage but from only about 25% sampled during the crusted stage.[104]

The availability of HSV-specific monoclonal antibody has facilitated the confirmation of virus isolated and the specification of viral type.[105] Specificity of these reagents corresponds well with typing of isolates by restriction enzyme analysis.[106]

Immunofluorescence.

Rapid, reliable direct methods have been developed to detect HSV in specimens obtained from mucocutaneous lesions. The most commonly used method is direct immunofluorescent staining.[106] The best method for specimen collection consists of unroofing a lesion to expose its base, removing cells with the blunt end of a cotton applicator stick, and streaking the sample onto a glass slide. With the use of fluorescein-conjugated monoclonal HSV antibody, direct staining of samples from lesion scrapings is 80% to 90% as sensitive as tissue culture isolation, with few false-positive reactions.[105,107] The Papanicolaou stain or Tzanck test no longer should be used to demonstrate cytologic changes in specimens obtained from suspected HSV lesions because these methods are less sensitive and nonspecific.[96]

Polymerase Chain Reaction.

PCR amplification of HSV DNA is a sensitive and specific diagnostic technique. The most important application of HSV PCR testing is in the diagnosis of HSV encephalitis. First reported in 1990,[108] subsequent studies from several laboratories confirmed the utility of PCR for the diagnosis of HSV encephalitis, with sensitivity and specificity consistently exceeding 90%.[80,109,110,111,112,113] PCR testing is considered the gold standard for the laboratory diagnosis of HSV CNS disease.[80]

PCR testing also is applied increasingly to blood or swab specimens collected from skin or mucosal sites. In one study of 63 infants, 83% had HSV DNA detected in blood, including 64% with CNS disease and 78% with SEM disease.[114] Performance characteristics for specimens collected from genital swabs are well defined,[115,116] but utility for skin and mucous membrane specimens from neonates suspected of having HSV has not been delineated.[117]

Serology

Before 2000, commercially available serologic assays were unable to distinguish between HSV-1 and HSV-2 antibodies, severely limiting their utility. Several type-specific serologic assays that reliably distinguish between immunoglobulin G (IgG) directed against HSV-1 and HSV-2 have since been approved by the US Food and Drug Administration. Many of these products are sold as kits that are used by clinical laboratories throughout the United States.

Monoclonal antibodies to the unique glycoprotein G (gG) of HSV-2 are used to capture protein from an HSV-infected cell sonicated in a solid-phase enzyme immunoassay or to prepare immunoaffinity-purified antigen for use in a dot blot assay.[118] Several additional tests that claim to distinguish between HSV-1 and HSV-2 antibody are available commercially, but high cross-reactivity due to the use of crude antigen preparations limit their utility,[119] and their use is not recommended.

Serologic tests that detect immunoglobulin G (IgG) antibodies cannot be used to diagnose recurrent HSV infection because a rise in antibody titer does not always occur. Primary infections can be confirmed by documenting seroconversion between acute and convalescent sera. A finding of IgM anti-HSV does not distinguish primary infection because reactivation can cause production of IgM antibody. HSV IgM assays also can have unacceptably high false-positive rates.

Treatment

Acyclovir or a derivative is the drug of choice for most HSV infections (Table 204.2).[120] Available formulations include topical ointment, oral tablets and liquid, and a preparation for intravenous delivery. The mechanisms of action, pharmacokinetics, dosages, and toxicities are detailed in Chapter 295.

TABLE 204.2

Systemic Acyclovir Therapy for Herpes Simplex Virus Infections

Type of Infection	Usefulness of Acyclovir Therapy
Orolabial	Possibly effective in severe, primary gingivostomatitis
	Marginally effective in recurrent infections
	Useful prophylactically in limited circumstances
Genital	Effective in treatment of first episode and, to a limited extent, of recurrent infections
	Effective in suppressing frequently recurrent attacks
Keratoconjunctivitis	Topical therapy beneficial (i.e., vidarabine, trifluridine, or acyclovir)
Cutaneous	Possibly effective in severe eruptions in those with compromised integument (e.g., burns, eczema)
	Possibly effective in whitlow infections
	Possibly effective prophylactically in limited circumstances
Central nervous system	Effective in reducing mortality and morbidity of encephalitis
Neonates	Effective in reducing mortality and morbidity rates
Compromised hosts	Effective for therapy of localized and disseminated infections
	Effective prophylactically against recurrent infection
	Resistance can emerge during long-term therapy

Orolabial Infection

In a study of 72 children with documented HSV primary herpetic gingivostomatitis, those who received oral acyclovir compared with placebo had a shorter duration of oral lesions (4 vs. 10 days) and earlier disappearance of fever, extraoral lesions, and drinking and eating difficulties. Duration of viral shedding also was significantly shorter in the group treated with acyclovir (1 vs. 5 days).[121]

Topical and oral acyclovir regimens have been evaluated in the treatment of recurrent herpes labialis. Topical acyclovir is not effective, and oral acyclovir, even when administered immediately at the onset of symptoms, affords marginal benefit in immunocompetent hosts.[122,123] Prophylactic administration of oral acyclovir may be useful in persons with frequently recurrent herpes labialis. In one randomized, double-blind, placebo-controlled study, 56 adults who previously experienced more than six recurrent episodes of herpes labialis in a year had a 53% reduction in clinical recurrences while receiving suppressive therapy with oral acyclovir.[124] Oral acyclovir also has had some benefit in reducing the extent of herpes labialis outbreaks in people who are prone to recurrences as a result of precipitants such as ultraviolet light exposure[49] and alpine skiing.[50]

Genital Infection

Acyclovir is useful in the management of patients with genital herpes, affording greatest benefit in first-episode primary infections and least benefit in recurrent genital herpes.[125,126] Valacyclovir and famciclovir, two antiviral agents with superior bioavailability for oral dosing compared with acyclovir, are safe and equally effective as acyclovir in the therapy of genital herpes.

Intravenous and oral administrations of acyclovir are more effective than topical therapy for primary and nonprimary first clinical episodes of genital HSV infections.[127] Oral administration is preferred for ambulatory patients because it is almost equal in efficacy to intravenous therapy. For primary infection, treatment reduces the duration of viral shedding and the time to complete healing by more than 1 week. In some studies, acyclovir therapy also shortens the duration of new lesion formation, pain, dysuria, and other symptoms.

Treatment does not prevent the establishment of latency or reduce the frequency of subsequent recurrences. Acyclovir has a beneficial although less pronounced effect on the course of recurrent genital herpes, resulting in a reduction of viral shedding and time to healing by 1 to 2 days; the effect on pain and itching is less.[127,128] Patients who tend to have more severe recurrent attacks, with multiple lesions persisting for more than 1 week, may benefit most from treatment. To ensure maximal benefit of therapy, patients may be provided a prescription for acyclovir tablets with instructions to begin the drug at the first indication of recurrence.

Long-term suppressive therapy with acyclovir has substantial value for frequently recurrent genital herpes. Recurrences are reduced by more than 75%, and when lesions occur, they are more likely to be mild. Although the frequency of asymptomatic shedding of HSV is substantially reduced during long-term suppressive therapy, shedding is not eliminated, and sexual transmission of the virus still can occur.[129]

Keratoconjunctivitis

Ocular infections caused by HSV usually are treated topically in conjunction with parenteral therapy in the neonate. Trifluridine or ganciclovir ophthalmic drops or ointment are used commonly (see Chapter 82). Oral acyclovir as prophylaxis against recurrent stromal keratitis appears to be effective at reducing long-term scarring from herpes infection.[130]

Cutaneous Infections

Sparse data exist regarding the treatment of cutaneous HSV infections in the normal host beyond the neonatal period. One study of nine evaluable subjects with recurrent lesions on the hand caused by HSV-2 concluded that oral acyclovir therapy had a beneficial effect on the duration of symptoms, signs, and culture positivity.[131] Treatment of cutaneous infections should be considered for burned patients or patients with eczema because infections in these hosts are potentially serious.

Central Nervous System Infection

In the first study that documented the efficacy of antiviral therapy of a CNS viral disease, vidarabine was shown to significantly improve the outcome of patients with HSV encephalitis.[132] The mortality rate was reduced from 70% among placebo recipients to 44% among drug recipients. A subsequent controlled intervention trial determined acyclovir to be superior to vidarabine.[76] The mortality rate was reduced from 54% among vidarabine recipients to 28% among acyclovir recipients. Survival was significantly affected by the age of the patient, the Glasgow Coma Scale score, and the duration of disease at onset of therapy. Age and the Glasgow score also significantly influenced morbidity observed 6 months after diagnosis. Outcome was best for those younger than 30 years of age with a Glasgow score greater than10 at the onset of therapy.[76]

A subsequent uncontrolled study of acyclovir therapy for HSV encephalitis in adults observed a worse long-term prognosis for subjects with a poor physiology score on hospitalization and for those for whom therapy was delayed more than 2 days after admission.[133] A low Glasgow score (but not necessarily presence of seizures) and age younger than 3 years appear to predict a poor outcome of HSV encephalitis in children treated with acyclovir.[112] Beyond the perinatal period, which is discussed later, acyclovir is given at a dose of 30 to 45 mg/kg/day in divided doses every 8 hours. Administration calculation as 500 mg/m^2/dose every 8 hours may be superior, particularly to avoid excessive dosing and renal injury associated with weights less than 50 kg.[134]

Other Infections

There are no controlled data regarding the effectiveness of antiviral therapy in patients with unusual manifestations of HSV infection. It is prudent to administer parenteral acyclovir to those with severe, life-threatening infections.

Intrauterine and Perinatal Infections

Antiviral therapy is beneficial for neonates with HSV infections. Vidarabine was the first agent with demonstrable benefit, reducing the mortality rate of disseminated or CNS infection from 70% among placebo recipients to 40% among vidarabine recipients. Acyclovir is now the drug of choice.[135]

An open-label evaluation of increasing dosages of intravenous acyclovir support the use of a 21-day course of 60 mg/kg/day to treat neonatal CNS and disseminated infection.[117,136] A 14-day course of 60 mg/kg/day is recommended for infants with SEM infection, even if HSV is detected in blood by PCR.

The best therapeutic results are obtained for localized SEM infection, with no deaths and with universally good neurodevelopmental outcomes.[95] In contrast, approximately 30% of infants with disseminated infection die.[136] There have been anecdotal reports of recovery from or survival of fulminant hepatic failure after liver transplantation and while receiving plasmapheresis of hemofiltration awaiting transplantation. About 5% of infants with CNS disease die despite therapy, and only 30% of survivors are normal at 1 year of age without additional suppressive therapy.[135,136] Recurrence of CNS symptoms with abnormal CSF findings occurs in about 8% of survivors of disseminated or CNS disease.[135] Six months of suppressive oral acyclovir (300 mg/m^2 per dose, 3 times daily) begun immediately after initial therapy of CNS infection improves neurodevelopment outcome assessed at 12 months of age and decreases the number of skin recurrences in all disease classifications of neonatal HSV.[137]

Although neonates with proven HSV infections should receive acyclovir promptly, the role of empiric acyclovir therapy is not clear. The relative risks of drug exposure and potential prolongation of hospitalization are weighed against the risk of delayed therapy.[138] Clinical settings in which empiric acyclovir therapy should be considered include the appearance of skin lesions typical of HSV while awaiting results of diagnostic tests, fever or other unexplained signs of infection in a neonate known to have been exposed to HSV at delivery, progressive clinical deterioration in an infant initially suspected to have bacterial sepsis for whom bacterial culture results are negative, and unexplained encephalitis in a neonate with unremitting seizures.[95,139]

When considering antiviral therapy in a neonate suspected of having HSV infection, the following specimens should be obtained: swab specimens from the mouth, nasopharynx, conjunctivae, and anus (i.e., surface cultures) for HSV culture and, if desired, for PCR testing; specimens of skin vesicles and CSF for HSV culture and PCR testing, respectively; whole blood for PCR testing; and serum samples for measuring alanine aminotransferase (ALT).[117] Guidance is available from the American Academy of Pediatrics (AAP) for the evaluation and treatment of infants born to women with active genital lesions.[140]

Compromised Hosts

Acyclovir is the drug of choice for the management of progressive mucocutaneous HSV in patients with compromised immune function. Therapy speeds healing of localized lesions and reduces the morbidity and mortality rates due to visceral dissemination.[141]

Emergence of HSV strains resistant to acyclovir is more common in the management of HSV infections in immunocompromised hosts than in normal hosts.[142] The prevalence of acyclovir-resistant strains among immunocompromised hosts varies according to the type and degree of immunosuppression, but it usually ranges between 5% and 10%.[143] HSV strains resistant to both acyclovir and foscarnet have been isolated from patients in whom sequential therapy with the two drugs failed.[144]

Prevention

Several candidate HSV vaccines have been developed from extracts of infected cells or recombinant virus glycoproteins, and newer vaccine approaches include DNA-based vaccines and replication-impaired viruses.[145–147] No tested vaccine has effectively prevented infection or establishment of latency,[31,145] and prevention of HSV infection depends on reducing transmission, acquisition, and reactivation of the virus. Complete prevention of transmission of genital HSV infection requires sexual abstinence because most infections are subclinical; consistent condom use provides some protection.

Reduction in the vertical transmission of HSV could be accomplished by reducing maternal infections or the likelihood of transmission to the neonate. Although suppressive acyclovir reduces clinical genital HSV reactivation, it does not eliminate asymptomatic viral shedding.[129] Because most women infected with HSV-2 have no history of genital herpes, it is unlikely that this method will be a practical approach to reducing the risk of infection of neonates born to previously infected mothers. Development of neonatal HSV disease in infants born to women on suppressive antiviral therapy has been reported.[148] Preventing the acquisition of new infections during pregnancy is complicated by the high proportion of genital infections transmitted from partners not known to be infected with HSV-2 and by the increasing incidence of genital HSV-1 infection.

Strategies to identify women who are shedding virus at parturition and thereby prevent transmission by cesarean delivery have been confounded by the need to recognize clinical lesions before progression of labor. These strategies are further frustrated by the occurrence of asymptomatic viral shedding, even in primary episodes. Use of prenatal cultures fails to predict shedding of virus at delivery and is not recommended.[149] Recognizing these limitations, the AAP has provided guidance for management of infants born to women with active genital lesions.[140]

Long-term suppressive therapy with acyclovir reduces reactivation of latent genital and orolabial HSV infections.[124,129] Once-daily suppressive valacyclovir therapy, administered to the infected partner of immunocompetent, heterosexual, monogamous couples who are discordant for HSV-2 infection reduces transmission of HSV to the uninfected partner.[150] Prophylactic acyclovir also has been used successfully in immunocompromised hosts, including those with bone marrow and renal transplants, cancer, and other immunodeficiencies. In these immunocompromised hosts, the frequency of HSV reactivation typically is reduced from 60% to 80% among placebo recipients to 0% to 10% among acyclovir recipients.[151] Availability of rapid virus identification and specific serologic tests could inform a graded approach in the future.

Key Points

Diagnosis and Management of Neonatal Herpes Simplex Virus Infections

Epidemiology

- The rate of neonatal infection is 1 case per 1700 to 1 case per 12,500 live births in the United States; the most reliable incidence rate is 1 case per 3200 live births.
- Infections acquired in utero (congenital) are rare, representing less that 5% of all cases.
- Most infections result from exposure at delivery to mothers shedding virus in the absence of symptoms.
- Maternal primary infection is associated with a much higher neonatal attack rate than maternal recurrent infection (50–60% vs. 2%).

Clinical Features

- There are three classic presentations
  - Skin, eye, and mucous membrane (SEM) infection characterized by skin vesicles at sites of trauma, mucosal lesions, and conjunctivitis (45% of cases of neonatal herpes simplex virus [HSV] disease)
  - Disseminated infection resembling bacterial sepsis with shock, liver failure, bleeding diatheses, and respiratory failure (25% of cases of neonatal HSV disease)
  - Central nervous system infection with irritability, lethargy, and typified by seizures (30% of cases of neonatal HSV disease)
- Usual age of onset is 5 to 21 days; SEM and disseminated infection typically is earlier (average, 10–12 days of life); central nervous system (CNS) infection typically is later (average, 17–19 days of life).
- High (>70%) mortality rate for untreated disseminated disease
- Reduced mortality rate with antiviral therapy but persistent morbidity, except for SEM infection

Diagnosis

- Culture and direct fluorescent antibody test of skin lesions, with or without polymerase chain reaction (PCR)
- Viral cultures of specimens obtained from skin and mucous membranes (i.e., surface sites), with or without PCR
- Cerebrospinal fluid analysis, including PCR
- Whole blood PCR

- Serum alanine aminotransferase (ALT) level
- Electroencephalography and brain imaging (i.e., computed tomography, magnetic resonance imaging, or cranial ultrasonography)

Treatment

- Intravenously administered acyclovir, 60 mg/kg/day in 3 divided doses for 14 days (SEM infection) to 21 days (disseminated and CNS infection) days; followed by orally administered acyclovir, 300 mg/m^2/dose × 3 doses/day (900 mg/m^2/day) for 6 months

Varicella-Zoster Virus

Ann M. Arvin

Varicella-zoster virus (VZV) is an alphaherpesvirus that is related most closely to herpes simplex virus (HSV). Primary infection with VZV causes varicella, commonly called *chickenpox.* VZV establishes latent infection in dorsal root ganglia and can reactivate to cause herpes zoster, often referred to as *shingles.* The double-stranded DNA genome of the virus encodes more than 70 proteins, including regulatory and virion structural proteins and envelope glycoproteins.[1,2] VZV replication usually involves synthesis of a viral thymidine kinase, making the virus susceptible to inhibition by acyclovir and related antiviral agents.

Pathogenesis

The pathogenesis of primary VZV infection (Fig. 205.1) begins with mucosal inoculation by virus transferred by the respiratory route or by direct contact with skin lesions of patients with varicella or herpes zoster. T lymphocytes from tonsils are highly susceptible to VZV infection. Because tonsillar crypts are lined with epithelial cells, VZV is presumed to gain access to lymphocytes in lymphoid tissues of the oropharynx, initiating a cell-associated viremia.

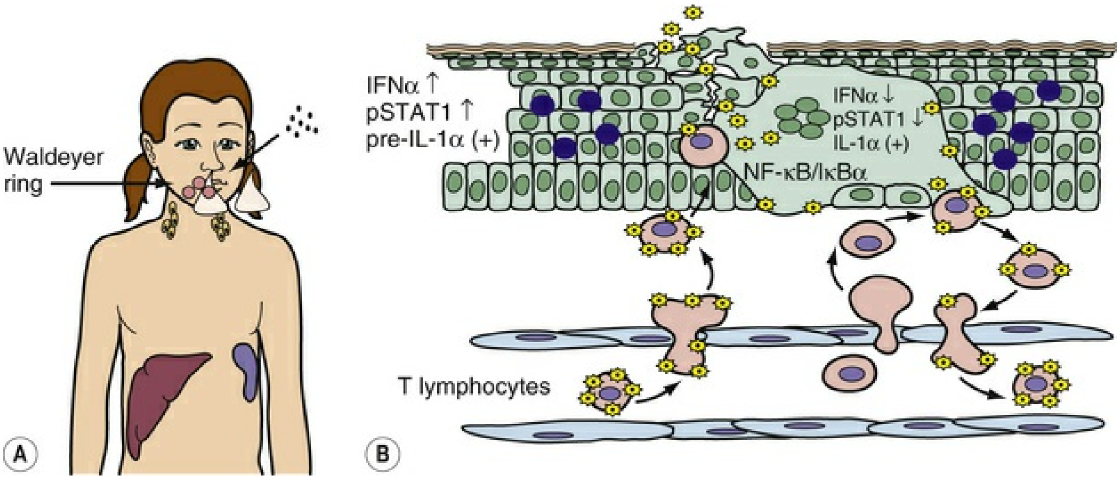

FIGURE 205.1 Modeling the pathogenesis of varicella-zoster virus (VZV) infection. (A) Primary infection with VZV is initiated by inoculation of respiratory epithelial cells, from which the virus gains access to highly permissive T lymphocytes in the tonsillar lymphoid tissues that comprise Waldeyer ring. During the 10- to 21-day incubation period, the virus is transferred to skin sites of replication and can replicate in reticuloendothelial organs (e.g., liver, spleen). Replication in epidermal cells causes the characteristic rash of varicella, which often is referred to as *chickenpox.* The virus reaches neurons in sensory ganglia during primary infection by the hematogenous route or by anterograde transport along neurons from skin lesions, where it establishes latency. (B) The formation of skin lesions that penetrate the skin surfaces requires 10 to 21 days because cell-to-cell spread of the virus after T lymphocyte transfer is countered by the potent innate antiviral responses of epidermal cells. Uninfected T lymphocytes that traffic through sites of VZV lesion formation may amplify VZV viremia. This well-regulated virus-host interaction in skin enhances opportunities for VZV transmission. IFNα, interferon α; pSTAT1, phosphorylated signal transducer and activator of transcription 1; pre-IL-1α, pre-interleukin-1α; NF-κB, nuclear factor-κB; ↓,decreased; ↑,increased; +, positive. (Modified from Cohen J, Straus S, Arvin A. Varicella-zoster virus. In: Fields BN, Knipe DH, Chanock R, et al. [eds]. Virology, 5th ed. Philadelphia, Lippincott-Raven, 2007, pp. 2774–2808.)

Studies in the SCID-hu mouse model of VZV pathogenesis show that the virus is transported by infected human T lymphocytes to skin xenografts within 24 hours. These experiments indicate that

VZV reaches skin early, but viral replication is countered by an innate antiviral response, characterized by interferon α/β (IFNα/β) production.[3] The 10- to 21-day incubation period appears to be the interval required for VZV to overcome this vigorous innate epidermal cell response (see Fig. 205.1). VZV viremia then is enhanced as uninfected T lymphocytes traffic through infected skin; replication in reticuloendothelial tissues also may contribute to amplification.[4]

VZV is carried back to respiratory mucosal sites during the late incubation period, as is evident from transmission to susceptible contacts exposed 24 to 48 hours before the appearance of cutaneous lesions in the index case.[5] The release of infectious virus into respiratory droplets is a pathogenic characteristic that differentiates VZV from other human herpesviruses. Latent infection of cells in dorsal root ganglia appears to be an invariable consequence of primary VZV infection. VZV persists predominantly or exclusively in neurons.[1]

VZV reactivation causes a localized vesicular rash that usually involves the dermatomal distribution of a single sensory nerve. Infectious VZV is present in herpes zoster lesions, but the virus does not appear to be released into respiratory secretions during reactivation. Although subclinical reactivation has been difficult to document, it is likely to occur unless maintenance of VZV latency is unusually effective compared with that of other herpesviruses.[1]

Reinfection with VZV is rare. Apparent second episodes of varicella are encountered in clinical practice, but laboratory diagnosis of the first episode usually is lacking, and vesicular rashes in childhood have many possible causes. Immunocompromised patients who have had varicella can have scattered cutaneous lesions suggesting reinfection, but most cases probably represent generalized atypical reactivation of latent virus without limitation to a dermatomal distribution.

Primary VZV infection elicits immunoglobulin G (IgG), IgM, and IgA antibodies directed against viral proteins.[6,7] Antibodies to VZV proteins have neutralizing activity and mediate destruction of infected cells by antibody-mediated cellular cytotoxicity. However, intact cellular immunity appears to be critical for the host to terminate viremia and virus replication at localized cutaneous sites.[8] Children with untreated agammaglobulinemia usually have uncomplicated varicella, whereas those with primary cell-mediated immunodeficiency diseases often die. Among children with malignancy, failure to acquire T lymphocytes that recognize VZV antigens correlates with persistent viremia and a high risk of visceral dissemination.[1] Early nonspecific immunity, such as natural killer cell cytotoxicity and the induction of IFNα production, also may be beneficial. Administration of exogenous IFNα has modified the severity of varicella in immunocompromised children.[9]

Primary VZV infection elicits memory T lymphocytes that exhibit helper and cytotoxic activity and continued production of specific antibodies. Persistent VZV immunity may be maintained by periodic re-exposure to the virus during annual epidemics or by repeated antigenic stimulation from subclinical reactivation. Diminished T-lymphocyte recognition of VZV antigens probably accounts for the increased risk of herpes zoster in immunocompromised children.[6] The short interval between primary and recurrent VZV infections in children with human immunodeficiency virus (HIV) infection and herpes zoster in young children after intrauterine or early postnatal varicella probably reflects poor induction of cell-mediated immunity.[10–13]

Epidemiology

VZV is restricted to the human host and is found worldwide. Before the licensure of varicella vaccine, an estimated 4 million cases of varicella occurred annually in the United States, which is equivalent to the annual birth cohort. In temperate climates, 90% to 95% of people acquire VZV in childhood as a result of annual varicella epidemics that occur during the late winter and spring. Adults with herpes zoster provide a continuing source for potential exposures to VZV, causing varicella in susceptible contacts who perpetuate transmission by the respiratory route and because of high titers of cell-free infectious virus in skin lesions.[1,2]

The attack rate for previously uninfected household contacts exposed to varicella is approximately 90%, whereas the transmission rate from less sustained exposures, such as in school classrooms or hospitals, is much less predictable and may be as low as 12% to 33%. For unexplained reasons, because the attack rates for varicella are much lower in tropical areas, more adults remain susceptible. Molecular analyses of virus isolates from various geographic areas do not suggest major alterations in the pathogen that could account for variations in geographic prevalence.[14]

Herpes zoster shows no seasonal variation. Herpes zoster is uncommon among children younger than 10 years of age (0.74 cases per 1000) compared with 3.4 cases per 1000 persons annually among people in the general population.[15] The incidence of herpes zoster is higher among children with prior VZV infection who are immunocompromised.[10] Primary VZV infection acquired in utero or during the first year of life also is associated with an increased risk of herpes zoster in early childhood.[11–13]

Wild-type strains of VZV that cause annual epidemics of varicella do not exhibit changes in virulence, as judged from the clinical severity of primary VZV infections from year to year. The risk of severe or life-threatening primary or recurrent VZV infections appears to depend on host factors rather than alterations of the virus.

Varicella

Clinical Manifestations

The incubation period of primary VZV infection is 10 to 21 days; symptoms most commonly begin between 14 and 16 days after exposure.[1,2] Varicella often is mild enough to escape diagnosis, but subclinical varicella is rare when exposed, susceptible children are examined prospectively during the period of risk.[16] About one half of children have prodromal symptoms, including fever, malaise, anorexia, headache, and occasionally, mild abdominal pain for 24 to 48 hours before the appearance of rash. Constitutional symptoms are prominent during the 24 to 72 hours after the first cutaneous lesions develop, but significant respiratory or gastrointestinal symptoms are unusual. Temperature elevation usually is moderate, ranging from 37.8°C to 38.8°C, but it can be as high as 41.1°C.

Varicella lesions appear first on the scalp, face, or trunk. The initial exanthem consists of erythematous macules that evolve to form clear, fluid-filled vesicles. Vesicles with a surrounding irregular margin of erythema often are described as resembling a dewdrop on a rose petal (Fig. 205.2). Varicella lesions in early stages usually are pruritic. After 24 to 48 hours, fluid becomes cloudy, and some lesions exhibit characteristic umbilication as crusting begins. As initial lesions begin to resolve, new crops form on the trunk and then the extremities. Late lesions may disappear without progressing to vesicle formation. Crusts are sloughed during the final phase as new epithelium is generated beneath the lesion site. Vesicles or small ulcers are common on mucous membranes of the oropharynx, conjunctivae, and vagina.

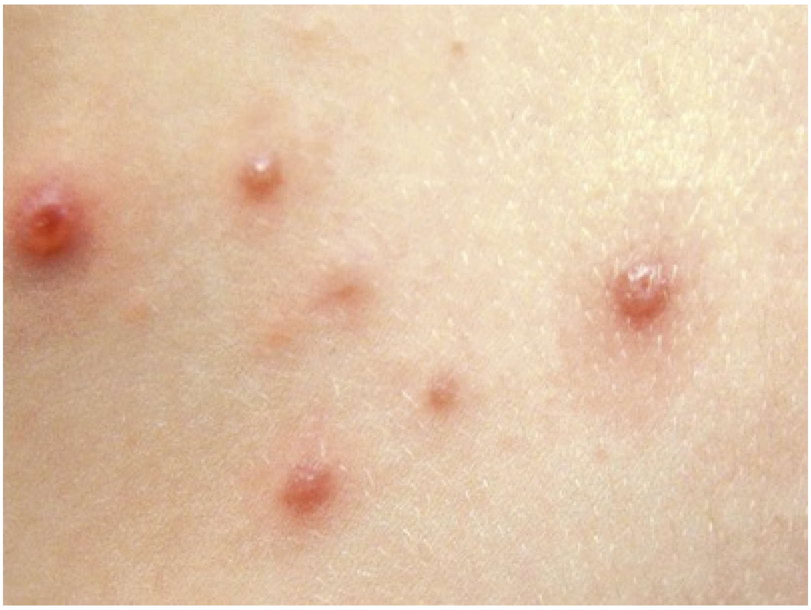

FIGURE 205.2 Early varicella lesions in various stages, including one called *dewdrop on a rose petal*.

In otherwise healthy children, new lesions appear for 1 to 7 days. In a prospective study of 521 children, more than one half demonstrated new lesions for 3 to 6 days, whereas only 1 child had new lesions for 7 days.[16] The total number of varicella lesions ranged from 12 to 1968 per child, with most children having more than 300 lesions. The duration of fever and new lesion formation is likely to be longer among children who have varicella after household exposure.[16,17] The severity of the illness also increases with increasing age. Preexisting skin trauma, such as eczema or scarring acquired during the incubation period (e.g., sunburn, surgery), exacerbates the exanthem at those sites. Extensive scarring is unusual, but hypopigmentation often persists for several weeks, especially in older children and children with darker skin. A single, shallow scar on the forehead is a common consequence of varicella because the initial lesions, which often occur along the hairline or eyebrow, involve deeper layers of the skin.

Varicella eruption must be differentiated from vesicular rashes associated with infections caused by other common pathogens, such as enterovirus or *Staphylococcus aureus*, or from rashes due to drug reactions, contact dermatitis, or insect bites. Early skin lesions may be particularly difficult to recognize clinically.

Complications in Healthy Children

Bacterial Infections

Secondary bacterial infections constitute the most common cause of morbidity in otherwise healthy children.[18–26] *S. aureus* and *Streptococcus pyogenes* are usual pathogens (see Fig. 118.3 in Chapter 118). Impetigo often is diagnosed, but it is difficult to differentiate from larger lesions caused by the virus alone. Bullous varicella can represent an unusual presentation of cutaneous VZV lesions or can be caused by bacterial superinfection.

Cellulitis is the most common complicating infection, but lymphadenitis and subcutaneous abscesses also occur. Cellulitis of the soft tissues of the neck can result in severe edema that compromises the airway. Life-threatening varicella gangrenosa associated with exotoxin A–producing *S. pyogenes* typically manifests as erythema, warmth, and pain of the skin around a single varicella lesion that enlarges rapidly over a few hours, often turning a dusky, dark red color. Extensive edema develops in the soft tissue around the lesion, producing necrotizing fasciitis (Fig. 205.3).

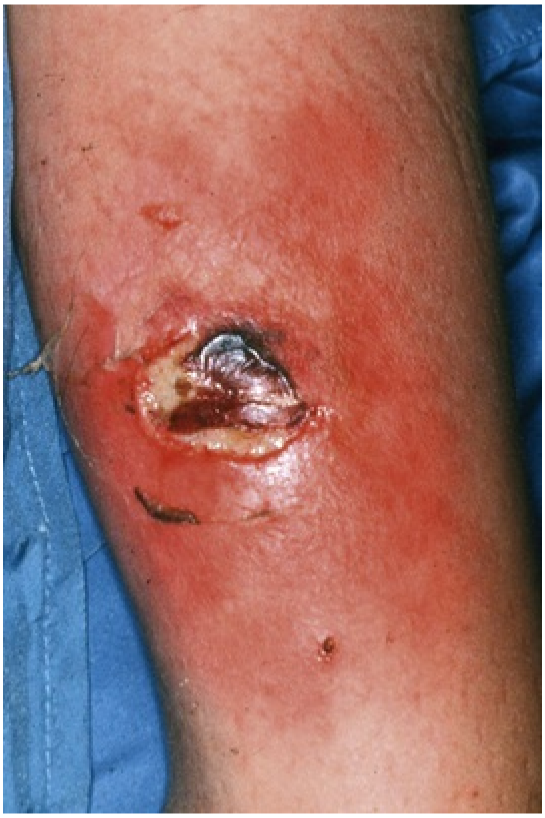

FIGURE 205.3 Group A streptococcal necrotizing fasciitis complicating otherwise mild varicella. (Courtesy of J.H. Brien ©.)

Varicella lesions provide a portal of entry, occasionally resulting in transient bacteremia or septicemia associated with high fever, cardiovascular collapse, and disseminated intravascular coagulopathy. Varicella can be complicated by community-associated methicillin-resistant *S. aureus* (CA-MRSA).[27] Hematogenous spread of *S. aureus* or *S. pyogenes* can result in focal infection, including pneumonia, arthritis, and osteomyelitis.

Neurologic Complications

Varicella is associated with a spectrum of central nervous system (CNS) complications in children. Neurologic complications are the second most common indication for hospitalization of immunocompetent children with varicella.[19–29] Varicella accounted for 13% of reported encephalitis cases of known cause in the United States between 1972 and 1977.[24] The incidence of CNS morbidity is highest among patients younger than 5 and older than 20 years of age.[20,26]

Neurologic manifestations include acute cerebellar ataxia, encephalitis, meningitis, isolated seizures, Guillain-Barré syndrome, transverse myelitis, acute disseminated encephalomyelitis, and ischemic stroke.[28,29] Signs of varicella encephalitis and of cerebellar ataxia have been described during the incubation period and after resolution of cutaneous disease, but in most cases, the neurologic symptoms occur between 2 and 6 days after onset of the rash.[7,28,29]

In two self-controlled case series of adults (with some children included), the stroke rate was increased for 6 months after chickenpox (fourfold increase among children)[30] and herpes zoster.[31] In a report of neurologic complications after chickenpox in 84 children hospitalized in Toronto from 1999 to 2012, 10 had arterial ischemic stroke. The median age was 4.25 years (range, 2–11.5 years), and the time from VZV exanthem to stroke was 16 weeks (range, 2–16 weeks). The median cerebrospinal fluid (CSF) cell count was 2 cells/mm^3 (range, 0–84), and the median protein level was 19 mg/dL (range, <10–133).[28]

The prognosis varies. Rapid improvement in acute encephalitis and cerebellar ataxia is usual. Reye syndrome can accompany varicella, but it has become rare because salicylates are contraindicated in children with varicella.[32]

Other Complications

In a prospective study of healthy children with varicella, 49% had mild elevations of aspartate aminotransferase (AST) (32–50 IU/L), and 28% had AST concentrations greater than 50 IU/L. Varicella hepatitis usually is subclinical, although some children with the highest elevations of AST (200–800 IU/L) have severe vomiting.[33] These cases can be differentiated from stage 1 Reye syndrome only by liver biopsy.

Acute thrombocytopenia, which is associated with petechiae and purpuric skin lesions, hemorrhage into the varicella vesicles, epistaxis, hematuria, and gastrointestinal bleeding, is a reported complication of varicella,[1] with cell counts remaining low for days to weeks. Postinfectious thrombocytopenia occurs 1 to 2 weeks after varicella, and bleeding complications can persist for an average of 5 weeks. Purpura fulminans due to arterial thrombosis is a rare but life-threatening complication of varicella.

Renal complications of primary VZV infection are rare.[1] Nephritis with hematuria, diffuse edema, and hypertension is described within 3 weeks after varicella exanthem; many cases represent poststreptococcal glomerulonephritis. Nephrotic syndrome and hemolytic uremic syndrome have been reported in a few children. Viral arthritis is an infrequent complication, with isolation of VZV from joint fluid. Arthritis resolves spontaneously within 3 to 5 days and is not associated with residual joint disease.

Other rare complications of varicella are myocarditis, pericarditis, pancreatitis, and orchitis. Many children have vesicular lesions on the eyelids and conjunctivae, but serious ocular complications of varicella are unusual.

Complications in High-Risk Populations

Progressive disease caused by primary VZV infection occurs in older adolescents and adults, immunocompromised children, pregnant women, and neonates.

Adolescents and Adults.

Clinically significant varicella pneumonia is rare in children, but otherwise healthy adults are more susceptible to pneumonia, which accounts for most of the increased morbidity and mortality rates attributed to primary VZV infection in this age group.[26,34,35] VZV pneumonia is associated with cough and dyspnea, usually beginning within 1 to 6 days (average, 3 days) after onset of the rash. Patients have cough, with or without cyanosis, pleuritic chest pain, and hemoptysis. Hypoxemia often is more severe than is suggested by the physical findings. The chest radiograph can be normal or can show diffuse bilateral infiltrates with small nodular densities, especially in the perihilar area.

Varicella pneumonia often is transient, resolving completely within 24 to 72 hours. In severe cases, interstitial pneumonia can progress rapidly to respiratory failure.

Pregnancy.

Varicella acquired during pregnancy can have severe consequences for the mother and fetus. Because most adults born in the United States are immune, the incidence of maternal varicella is low, affecting 0.7 in 1000 women in a study of 30,000 pregnancies in the 1960s.[36] Varicella pneumonia is the major cause of maternal morbidity and mortality.[37–39] Spontaneous abortion, fetal demise, and premature delivery can occur, although the frequency of these complications is low.[37–40]

In rare instances, maternal varicella results in congenital varicella syndrome (Box 205.1).[2] The highest risk of severe embryopathy accompanies varicella acquired during the first 20 weeks of gestation and is estimated to occur in less than 2% of cases of maternal varicella.[2,36–41] Infants affected after maternal varicella contracted later in pregnancy are described, but defects are limited to cutaneous scarring, diminished limb growth, or unilateral ocular defects.[41]

Box 205.1

Clinical Manifestations of the Congenital Varicella Syndrome

Skin

Cutaneous defects

Cicatricial scars

Hypopigmentation

Bullous lesions

Chorioretinitis

Microphthalmia

Anisocoria

Central Nervous System

Intrauterine encephalitis with cortical atrophy

Seizures

Mental retardation

Urinary Tract

Hydronephrosis or hydroureter

Gastrointestinal Tract

Esophageal dilation or reflux

The most striking anomalies of the congenital varicella syndrome are unusual cutaneous defects with cicatricial skin scars, atrophy of an extremity, and evidence of damage to the autonomic nervous system. Many affected infants have microcephaly and cortical atrophy due to probable intrauterine VZV encephalitis. Seizures and global developmental delay are common sequelae. Chorioretinitis, microphthalmia, and cataracts also occur. Dysfunction of the autonomic nervous system produces neurogenic bladder, hydroureter, hydronephrosis, and severe gastroesophageal reflux with recurrent aspiration pneumonia.[42] Limb anomalies and other sequelae of intrauterine varicella infection can be detected with fetal ultrasonography.[43] Some intrauterine infections are asymptomatic, as shown by VZV-specific immunity or the occurrence of herpes zoster in infancy without an intervening episode of varicella.

When maternal varicella occurs during the last few days of gestation, the infant is at risk for neonatal varicella infection, with an attack rate of approximately 20%.[43,44] Infants who are born at least 5 days after the onset of varicella infection in the mother are not at high risk. Although these infants have lesions at birth or within the first 5 days of life, they are protected from severe disease transplacental transfer of maternal IgG anti-VZV. Those who are born within 4 days after or 2 days before the onset of maternal varicella can exhibit progressive varicella infection, with an untreated mortality rate of 30%. Exposure of an infant to nonmaternal contacts with varicella rarely causes varicella in the infant because most infants are born to seropositive mothers.

Rare cases of postnatally acquired varicella that have occurred in infants younger than 2 months of age who were born to seronegative mothers do not suggest a severe course. Occasionally, infants born to immune mothers who have close household exposure to varicella have mild varicella or subclinical infection that manifests as herpes zoster later in childhood.[11–13]

Malignancy.

Without effective antiviral drugs, 32% to 50% of children with lymphoproliferative malignancies or solid tumors experience visceral dissemination. Varicella pneumonia occurs in 20% of cases, and mortality rates range from 7% to 17%.[45–48]

Progressive disease is characterized by a prolonged period of new lesion formation, pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy.[1,2] The risk of progressive varicella is highest if chemotherapy is given during the incubation period, especially within 5 days before the appearance of the rash, and when the absolute lymphocyte count is less than 500 cells/mm^3 at the onset of the rash.

Pneumonia is the most common life-threatening complication. In one large series, all varicella-related deaths occurred within 3 days after the diagnosis of varicella pneumonia.[48] Hemorrhage into cutaneous lesions or severe abdominal or back pain is associated with potentially life-threatening varicella. Some patients experience progressive encephalitis with coma, but varicella encephalitis is rarely the immediate cause of death among immunocompromised patients. The syndrome of inappropriate secretion of antidiuretic hormone can accompany disseminated varicella with or without clinical encephalitis. Disseminated VZV infection in children with cancer also can be associated with pancreatitis, necrotizing splenitis, esophagitis, and enterocolitis.

Other Immunodeficiency States.

Children who acquire varicella after organ transplantation are at risk for progressive VZV infection unless they receive antiviral therapy.[48–52] Thrombocytopenia and hepatitis are the major clinical complications in renal transplant recipients. Children receiving long-term, low-dose corticosteroid therapy for asthma usually are not at risk for serious varicella. However, fatal varicella is described in patients who receive higher doses of prednisone, especially during the incubation period.[53]

Untreated varicella is severe or fatal in children with defects of T-lymphocyte function, including severe combined immunodeficiency, cartilage-hair hypoplasia (i.e., short-limbed dwarfism), Wiskott-Aldrich syndrome, and ataxia telangiectasia.[6] Unusual clinical findings in varicella, including lesions that develop a unique hyperkeratotic appearance and formation of new lesions for weeks or months, have been described in children with HIV infection.[54–57]

Herpes Zoster

Clinical Manifestations

Herpes zoster is unusual in children. When it occurs, the cutaneous eruption is mild, and symptoms of acute neuritis are minimal or absent. Herpes zoster is characterized by vesicular lesions clustered unilaterally in the dermatomal distribution of one or more adjacent sensory nerves (Fig. 205.4). Discrete vesicles resembling varicella lesions appear first and then enlarge and coalesce as the exanthem evolves. The rash is preceded or accompanied by localized pain, hyperesthesias, and pruritus. In healthy people, formation of new lesions in the primary dermatome stops within 3 to 7 days, and crusting occurs within 2 weeks.

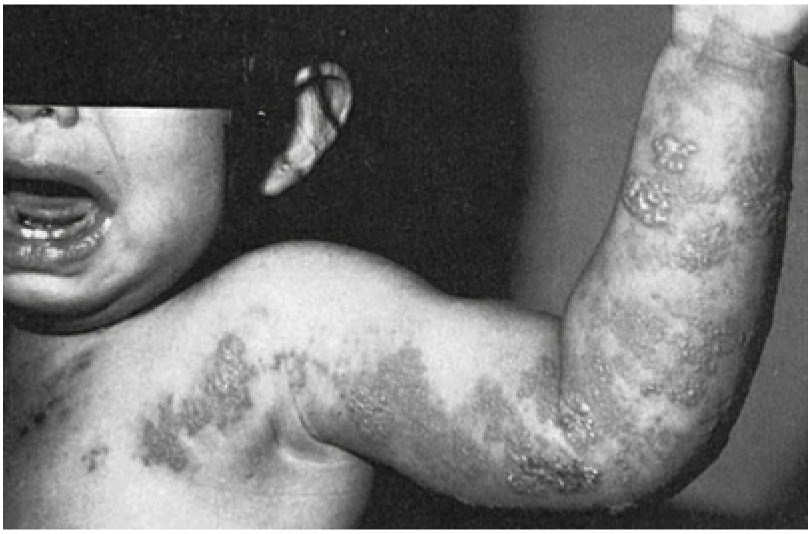

FIGURE 205.4 Characteristic unilateral dermatomal distribution of discrete and coalescent vesicles in a 10-month-old child with herpes zoster.

VZV reactivation without skin lesions (i.e., zoster sine herpete) has been diagnosed in adults with idiopathic facial palsy or other pain syndromes. It occurs rarely in children.

Complications

Healthy children are not at risk for the complication of postherpetic neuralgia, which causes debilitating chronic pain in adults.[1] Complications of herpes zoster involving cranial nerves include conjunctivitis, dendritic keratitis (Fig. 205.5), anterior uveitis, iridocyclitis, retinitis, and facial palsies.[58] Neurogenic bladder dysfunction or ileus with intestinal obstruction can accompany lumbosacral herpes zoster. Transverse myelitis is a rare, severe complication that produces transient or persistent paralysis and sensory deficits.

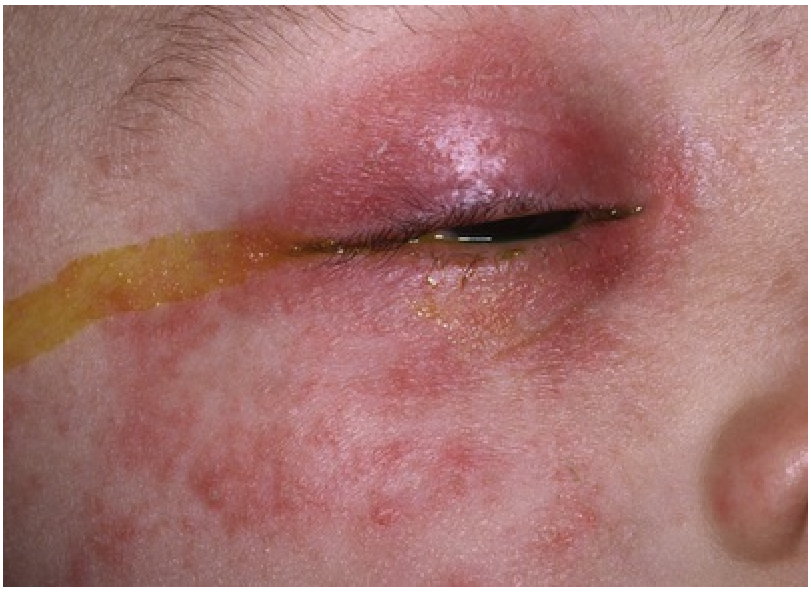

FIGURE 205.5 Zoster with keratitis in an otherwise healthy child. (Courtesy of J.H. Brien ©.)

Herpes zoster in immunocompromised children can result in severe local dermatomal infection and visceral dissemination.[48] Cutaneous lesions outside the primary dermatome or an adjacent dermatome indicate VZV viremia, which is a risk factor for visceral dissemination. Hematogenous spread can cause pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy. Atypical nonlocalized herpes zoster occurs in severely immunocompromised patients, especially bone marrow transplant recipients, and the widely scattered vesicular lesions cannot be distinguished from varicella.

Severely immunocompromised children, particularly those with HIV infection, can have unusual chronic or relapsing cutaneous disease, retinitis, and CNS infections that occur without associated cutaneous disease or that progress after resolution of signs of herpes zoster.[54–57] Unusual neurologic complications (e.g., multifocal leukoencephalopathy) are described in patients with prolonged, severe immunosuppression.

Laboratory Findings and Diagnosis

Laboratory tests are not necessary for management of previously healthy children with varicella. Abnormal laboratory values are common. The total white blood cell count often is decreased during the first 72 hours of rash, followed by lymphocytosis; lymphoblasts and prolymphocytes can be seen in peripheral blood.[6] Slight to moderate abnormalities of serum hepatic enzyme values are common.

The CSF in patients with neurologic complications of varicella usually shows a mild lymphocytic pleocytosis with fewer than 100 cells/mm^3 and a slight to moderate elevation of the protein level (<200 mg/dL). The glucose concentration usually is normal. CSF pleocytosis and protein concentrations are higher in patients with encephalitis than in those with cerebellar disease.[28] Patients with uncomplicated herpes zoster can have CSF pleocytosis consisting predominantly of mononuclear cells and an elevated protein concentration.

A definitive diagnosis is desirable when varicella or herpes zoster is suspected in immunocompromised children. Isolation of VZV in culture has been a gold standard but is difficult, and the time to viral identification is 3 to 7 days. Rapid diagnosis of cutaneous VZV infection is accomplished by obtaining epithelial cells from the base of a newly formed vesicle and staining the specimen with immunohistochemical reagents that detect viral proteins in infected cells or by enzyme immunoassay methods to detect VZV antigens in solubilized preparations of cells and vesicle fluid from cutaneous VZV lesions. VZV can be detected in clinical specimens through in situ hybridization or polymerase chain reaction (PCR) testing.[59,60] Interpretation of positive results as causal can be difficult to distinguish from subclinical reactivation. In the case of fetal exposures, interpretation of PCR results is difficult because infection can occur without damaging the fetus.[37,38,40]

IgG anti-VZV levels are detectable in most patients within 3 days of onset of symptoms, and they exhibit a marked increase during convalescence. IgG anti-VZV persists for life after primary infection and is not useful in most diagnostic settings. Testing for IgM anti-VZV should not be used for clinical diagnosis because false-positive and false-negative results occur with all commercially available methods.

Assays for IgG anti-VZV are valuable to determine the immune status of people whose clinical history of varicella and immunization is unknown or equivocal; to evaluate the risk of primary VZV infection in exposed people or the risk of reactivation in patients who are receiving immunosuppressive therapy; and to guide decisions about the need for varicella immunization.[61,62] Immunofluorescence testing performed with unfixed, VZV-infected cells is a highly sensitive method for detecting IgG anti-VZV, but it involves complex methodology, and immunofluorescence testing using fixed cells is subject to false-positive interpretation.

Commercial enzyme immunoassay methods to assess VZV antibodies usually have a high degree of specificity, generating few false-positive results, but they are not as sensitive as research methods. Between 10% and 15% of people who are immune to VZV may be identified as susceptible. Latex agglutination methods are somewhat more sensitive and specific than enzyme immunoassay, providing a simple and rapid alternative for detecting IgG anti-VZV.[63,64]

A positive history of varicella predicts immunity in more than 95% of people. The likelihood of immunity in an adult born before 1980 with a negative history also is high, unless the patient's childhood was spent in an area such as the tropics, where varicella is less common. Serologic testing after varicella vaccination is not advisable because false-negative results using commercially available serologic methods may be more common than is observed in naturally immune people.

Treatment

Acyclovir is used most commonly to treat varicella and herpes zoster (Box 205.2).[17,45,46,65] Famciclovir and valacyclovir, nucleoside analogues that are structurally similar to acyclovir, are absorbed more efficiently after oral administration. These drugs have been licensed for treatment of herpes zoster in adults, with some extrapolation of dosing for children.[66]

Box 205.2

Use of Acyclovir for the Treatment of Varicella

Acyclovir Indicated

Patients

Malignancy, bone marrow or organ transplantation, high-dose steroid therapy

Congenital T-lymphocyte immunodeficiencies

Human immunodeficiency virus infection

Neonatal varicella after maternal varicella beginning within 5 days before or 2 days after delivery

Associated pneumonia or encephalitis

Administration

Initiate as soon as possible after initial lesions appear

Intravenous route[a]

Dosage

<1 year old: 30 mg/kg/day divided into 8 hourly doses given as a 1-hour infusion

>1 year old: 1.5 g/m^2/day divided into 8 hourly doses given as a 1-hour infusion

Duration: 7 days or until no new lesions have appeared for 48 hours

Acyclovir Optional

Patients

Chronic cutaneous disorders

Chronic diseases that may be exacerbated by acute VZV infection, such as cystic fibrosis or other pulmonary disorders, diabetes mellitus, or disorders requiring chronic salicylate therapy or intermittent corticosteroid therapy

Otherwise healthy children, especially those >12 years old or secondary household contacts

Administration

Initiate within 24 hours after the initial lesions appear

Oral route

Dosage

80 mg/kg/day divided into 4 doses (maximum of 800 mg/dose)

Duration: 5 days

---

[a] Selected patients who are considered at relatively low risk for varicella-zoster virus (VZV) dissemination can be treated with oral acyclovir and carefully monitored for progression.

Acyclovir is metabolized to the triphosphate form within VZV-infected cells. The phosphorylated compound functions as a competitive inhibitor and chain terminator of viral DNA polymerase. The antiviral activity of acyclovir is lower against VZV than against HSV. Ensuring that plasma concentrations are several-fold higher than in vitro inhibitory concentrations for most VZV isolates requires the use of high-dose acyclovir. Prolonged exposure of VZV isolates to acyclovir in vitro selects for thymidine kinase–negative mutants. Resistant strains of VZV have been recovered from severely immunocompromised patients who have been treated with acyclovir for repeated or chronic episodes of VZV infection.[66]

Varicella

Healthy Children and Adolescents.

Placebo-controlled clinical studies show that orally administered acyclovir diminishes the clinical symptoms of varicella in otherwise healthy children, adolescents, and adults when administered within 24 hours after the appearance of the initial cutaneous lesions.[17,67–69] In a study in which healthy children 2 to 12 years old were treated with 80 mg/kg/day (20 mg/kg per dose 4 times daily; maximum of 800 mg/dose) of acyclovir administered orally for 5 days, reductions in fever, pruritus, number of days of new lesion formation, and total number of cutaneous lesions were observed.[17] Acyclovir recipients also had fewer lesions that progressed from the maculopapular to the vesicular stage. Among younger children, immediate acyclovir therapy converted all cases of varicella to the mildest form of illness that might be observed without treatment (i.e., new lesions ≤3 days and total lesions <300).[17]

The impact of orally administered acyclovir on varicella in adolescents (i.e., 13–18 years of age) and in young adults was similar to that observed in young children. However, the effects have more clinical relevance because varicella is more severe among untreated patients in these older age groups.[67] Adolescents in the treated group were significantly less likely to have residual hypopigmented skin lesions at 4 weeks, suggesting that drug therapy minimized the spread of virus to cells deeper in the dermis. Although study groups were not large enough to document it, the evidence of diminished viremia and cutaneous viral replication supports the assumption that oral acyclovir can reduce the risk of varicella pneumonia in otherwise healthy adults. In adults and young children, acyclovir must be given within 24 hours after initial lesions to have demonstrable clinical efficacy.[32] All patients with varicella pneumonia should receive acyclovir intravenously.

Oral acyclovir is licensed for the treatment of varicella in healthy children and adults. Acyclovir therapy does not have a detrimental effect on the host response to VZV.[17,68] The American Academy of Pediatrics recommends that acyclovir be considered for unvaccinated patients with varicella who are 12 years of age or older, have chronic cutaneous or pulmonary diseases requiring long-term salicylate therapy, or are being treated with short or intermittent courses of corticosteroids or aerosolized corticosteroids.[65]

Immunocompromised Patients.

Acyclovir therapy diminishes the clinical severity of varicella in immunocompromised children by terminating cell-associated viremia despite impaired host responses.[70,71] Early antiviral therapy prevents progressive varicella and visceral dissemination. The mortality rate is decreased because the risk of varicella pneumonia is reduced. When acyclovir was given intravenously to children with malignancy in a placebo-controlled trial, the incidence of varicella pneumonia was decreased from 45% to 0%.[72] The dosage of acyclovir for varicella in high-risk patients is 1.5 $g/m^2/day$, administered intravenously in 3 divided doses for 7 days.

The optimal use of acyclovir in immunocompromised children with varicella requires initiation of treatment within the first 24 to 72 hours after the onset of rash. Intravenous administration should be started immediately if the patient has signs of pneumonia, hepatitis, thrombocytopenia, or encephalitis. Waiting to initiate treatment until prolonged new lesion formation has been documented is inappropriate because visceral dissemination occurs during the same period. In addition to preventing life-threatening dissemination, early acyclovir therapy can be expected to minimize cutaneous disease, possibly reducing the risk of secondary bacterial infections.

Oral administration of acyclovir, famciclovir, or valacyclovir has not been evaluated in clinical trials for high-risk children. The use of these agents should be considered only in selected patients with minimal immunosuppression, and it requires careful follow-up during the illness.

Herpes Zoster

Acyclovir has been effective for the treatment of herpes zoster in healthy and immunocompromised patients participating in placebo-controlled trials.[65,70] For patients who are at high risk for disseminated disease, the dose of acyclovir is 1.5 g/m^2/day or 30 mg/kg/ day divided into doses every 8 hours and given intravenously. Acyclovir is given for a total of 7 days or for 2 days after the cessation of new lesion formation, whichever is longer.

Acyclovir therapy initiated within 72 hours after the onset of herpes zoster reduces the duration of new lesion formation from 1 or more weeks to approximately 3 days. Antiviral treatment is associated with earlier cessation of acute pain and crusting and with complete healing by 2 to 3 weeks. Although early acyclovir treatment is likely to produce the best results, clinical benefit is observed even when therapy is delayed for more than 3 days in immunocompromised patients. Relapse of herpes zoster is a clinical problem in some immunocompromised patients, but most patients show a response to treatment with a second course of acyclovir. Oral acyclovir administration for herpes zoster in high-risk patients is reserved for patients who are considered unlikely to develop visceral dissemination.

Famciclovir and valacyclovir are effective oral agents for herpes zoster.[71,73] Ganciclovir has in vitro activity against VZV that is equivalent to acyclovir but is more toxic. Foscarnet is the drug of choice for the treatment of infections due to acyclovir-resistant VZV.[74]

Prevention

Preventing the transmission of VZV to susceptible people is difficult because infected people are contagious for 24 to 48 hours before the onset of clinical signs of varicella. For example, restrictions on attendance do not alter the course of varicella epidemics in schools.[75] Infection control practices, including caring for infected patients in isolation rooms with filtered air systems, are essential in hospitals that care for immunocompromised children. Filtration is necessary because VZV has been transmitted to hospitalized patients by airflow systems, and VZV can be detected in air samples by PCR testing.[76–78]

Susceptible healthcare personnel who have had a close exposure to varicella should not care for high-risk patients during the incubation period because secondary cases have occurred in this clinical setting. Similar precautions should be taken in vaccinated healthcare personnel who have had close exposures; breakthrough varicella can occur in adults, although the infection is much less severe. Serologic testing is not helpful in these people because breakthrough infection can occur in those with or without detectable levels of IgG anti-VZV.

Passive Antibody Prophylaxis

Varicella-zoster immune globulin (VZIG), which was prepared from high-titer immune human serum, reduced the attack rate for varicella when given just after exposure.[79–82] Breakthrough infections occurred, but the extent of exanthem and risk of varicella pneumonia were diminished. VZIG given after the appearance of varicella rash did not alter the disease process.

VZIG is no longer available in the United States. The alternative preparation, VariZIG, which is a high-titer VZV immune globulin, is available through an investigational new drug expanded access program (FFF Enterprises, Temecula, CA; 24-hour phone: 800-843-7477).[83] VariZIG also may be obtained from ASD HealthCare (Frisco, TX; phone: 800-746-6273. Immune globulin intravenous (IGIV, 400 mg/kg) may be given to high-risk patients exposed to varicella as an alternative to VariZIG.[69,83,84]

The decision to administer VariZIG or IGIV depends on three factors: the likelihood that the exposed person is susceptible to VZV, the probability that the exposure will result in infection, and the likelihood that VZV infection will be severe or complicated[69] (Box 205.3). VariZIG or IGIV should be given to susceptible high-risk patients within 96 hours and, if possible, within 48 hours after a close exposure to a person with varicella or herpes zoster.

Box 205.3

Use of Varicella-Zoster Antibody After Exposure

Patients at Risk

Immunocompromised child with no history of varicella or varicella immunization

Pregnant woman with no history of varicella and no antibody to varicella-zoster virus (VZV)[a]

Newborn infant whose mother had onset of chickenpox within 5 days before or 48 hours after delivery

Hospitalized preterm infant <28 weeks' gestation or birth weight <1000 g, regardless of maternal history of chickenpox or VZV serostatus

Hospitalized preterm infant ≥28 weeks' gestation whose mother lacks a reliable history of chickenpox or lacks antibody to VZV

Criteria for Close Exposure

Household: residing in the same household

Playmate, schoolmate, or other: face-to-face indoor contact[b]

Hospital: varicella

- In the same 2- to 4-bed room or in an adjacent bed in an open ward
- Face-to-face contact with a contagious staff member, visitor, or other person[b]

Hospital: herpes zoster

- Intimate contact (e.g., touching, hugging) with a person deemed contagious
- Newborn infant
- Onset of chickenpox in the mother within 5 days before or 48 hours after delivery (varicella-zoster immune globulin [VariZIG] is not indicated if mother has herpes zoster)

Administration of Varizig

VariZIG should be administered as soon as possible and at least within 96 hours after exposure.

Dose: 1 vial (125 U)/10 kg of body weight (maximum of 5 vials) by intramuscular injection; VariZIG cannot be given intravenously. Minimum dose is 125 U

---

[a] Serologic testing is recommended if results can be obtained immediately because most adult women with no history of varicella are immune.

[b] Experts differ about estimates of minimum duration of contact to be considered significant (5 minutes to >1 hour).

Data from American Academy of Pediatrics. Varicella-zoster infections. In: Pickering LK (ed). 2009 Red Book: Report of the Committee on Infectious Diseases, 28th ed. Elk Grove

Village, IL, American Academy of Pediatrics, 2006, p. 717; Centers for Disease Control and Prevention (CDC). A new product (VariZIG) for postexposure prophylaxis of varicella available under an investigational new drug application expanded access protocol. MMWR Morb Mortal Wkly Rep 2006;55:209–210.

Passive antibody prophylaxis is recommended for immunocompromised children, pregnant women, and neonates exposed to mothers with onset of varicella 5 or fewer days before delivery or within 48 hours after delivery.[42,82] VariZIG or IGIV is not indicated for healthy, term infants exposed postnatally, including those whose mothers' rash developed more than 48 hours after delivery. If possible, pregnant women should be tested for IgG anti-VZV before passive antibody administration because many adults with no clinical history of varicella are immune.

The administration of passive antibody prophylaxis does not eliminate the possibility of disease in high-risk patients.[44,82] The incidence of varicella despite VZIG prophylaxis was significantly higher after household exposures. In one study, passive administration of antibody preparations to immunocompromised children lowered the risk of severe varicella significantly, but 11% of the children still experienced pneumonitis.[45] Immunocompromised patients who have received high-dose IGIV (100 to 400 mg/kg) for other indications within 2 to 3 weeks before the exposure can be expected to have serum antibodies to VZV.[84] Because passive antibody titers decline by 2 weeks in some patients and by 4 weeks in most, a second dose should be given if a new exposure occurs more than 2 weeks later. Although the risk of VZV transmission from a person with herpes zoster is low, close contact between a susceptible high-risk patient and a person with herpes zoster justifies administration of VariZIG or IGIV.

Administration of VZIG can prolong the incubation period to 28 days; whether other passive antibody preparations will have this effect is not known. Passive antibody prophylaxis does not reduce the risk of VZV reactivation in high-risk populations or alter the clinical course of herpes zoster when given after the onset of symptoms.

Antiviral Prophylaxis

Although the use of acyclovir as prophylaxis against varicella has been described, it is not recommended because data are limited. In one study, the attack rate after household exposure was reduced to 16% when oral acyclovir (40 or 80 mg/kg/day in 4 divided doses for 7 days) was given to 25 healthy children beginning 7 to 9 days after the onset of varicella in the index case; seroconversion was observed in 84% of the patients.[85]

Additional data about acyclovir prophylaxis is needed because of the potential for interference with the host response, which may predispose to early recurrent infection or incomplete protection from subsequent exposures, and enhanced selection of resistant VZV. In most circumstances, the objective of modifying the severity of varicella can be achieved by following the patient closely and giving the drug immediately after the onset of symptoms. However, if follow-up cannot be ensured, chemoprophylaxis with acyclovir (80 mg/kg/day divided into 4 doses of 20 mg/kg, for 7 days) may be considered.

Acyclovir prophylaxis reduces the risk of recurrent VZV infection in bone marrow transplant recipients, but VZV reactivation occurs when acyclovir is discontinued. Acyclovir prophylaxis for herpes zoster is not essential because the prompt initiation of acyclovir for the treatment of recurrent VZV infections is effective in reducing morbidity and mortality rates for immunocompromised patients.[65] In some centers, acyclovir prophylaxis is used in the early months after transplantation, and it sometimes is continued for 12 months. However, prolonged low-dose administration of acyclovir has the potential to result in the emergence of drug-resistant VZV.

Varicella Vaccine

The development and initial clinical evaluation of a live, attenuated varicella vaccine were first reported by Takahashi in 1974. Live, attenuated varicella vaccine, made from the Oka strain, was the first human herpesvirus vaccine licensed for clinical use in several countries. The varicella vaccine was licensed in the United States in 1995, and 2 doses are recommended for universal administration in early childhood.[86,87] The recommendations and contraindications for these are outlined in Box 205.4.

Box 205.4

Indications and Contraindications for

Administration of Live, Attenuated Varicella Vaccine

Indications

- Age 12 months to 13 years: 2 doses at minimum 3-month interval in patients susceptible according to history[a]
- Age 13 years to young adult:; 2 doses at 4–8-week interval; consider serologic testing to evaluate susceptibility
- Postexposure prophylaxis for unvaccinated people without other evidence of immunity

Contraindications

- Congenital or acquired immunodeficiency or systemic immunosuppression therapy, blood dyscrasia
- Leukemia, lymphoma, other malignancy until chemotherapy has been terminated for at least 3 months[b]
- Symptomatic human immunodeficiency virus infection
- High-dose systemic corticosteroids (≥2 mg/kg/day of prednisone for ≥1 month or 20 mg daily)
- Pregnancy
- Anaphylaxis to neomycin or other vaccine component

Precautions

- Intercurrent illness (if more than minor)
- Immunoglobulin or other blood products within 3 to 11 months, depending on the product (similar to measles vaccine)
- Salicylates should be avoided for 6 weeks after vaccination[c]
- Thrombocytopenia

Based on Committee on Infectious Diseases, American Academy of Pediatrics. Prevention of varicella: recommendations for use of varicella vaccine in children, including a recommendation for a routine 2-dose varicella immunization schedule. Pediatrics 2007;120:221–231.

---

[a] One dose is 0.5 mL SC. Simultaneous administration with measles-mumps-rubella (MMR) vaccine is acceptable but requires the use of separate syringes and injection sites. Quadrivalent measles-mumps-rubella-varicella (MMRV) is associated with a higher risk of febrile seizures after the first dose.

[b] Vaccination of children with acute lymphocytic leukemia who are in remission and who do not have evidence of immunity to varicella should be undertaken only with expert guidance and with availability of antiviral therapy in case complications ensue.

[c] Unless the risk of natural varicella is considered to outweigh the theoretical risk of Reye syndrome.

From Marin M, Güris D, Chaves SS, et al. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Wkly Rep 2007;56(RR-04):1–40.

Since the introduction of varicella vaccine, there has been a 90% to 95% reduction in the US rates of incidence, morbidity, and hospitalizations due to varicella. Fifteen years after introduction of vaccination, there is no evidence of a shift in the burden of disease to older age groups.[88]

Before its licensure, the investigational live, attenuated varicella vaccine (i.e., Oka-Merck strain) was administered to more than 7000 children and more than 1600 healthy susceptible adults in the United States.[89] The vaccine, given as a high-titer preparation, induced protection against household exposure, with an efficacy rate of more than 95% in an initial placebo-controlled study.[90–93] Subsequent evaluations of children immunized in the clinical trials demonstrated high seroconversion rates by the glycoprotein enzyme immunoassay (gpEIA) method. Mild breakthrough infections were observed in some children, but disease was modified to fewer than 50 cutaneous lesions without associated fever in most cases.[94,95]

In 2163 vaccinees evaluated at one center, varicella developed in 114 children at a median of 44 months after immunization. The median number of skin lesions was 18, and the incidence of transmission to other vaccinated children in the household from these cases was 12%.[94] Persistence of VZV immunity over an interval of 1 to 6 years was documented in 94% to 100% of children by means of assays for IgG antibodies and T-lymphocyte proliferation to VZV.[95–97] Sustained protective efficacy of 95% was shown among vaccine recipients from the original placebo-controlled trial, who were monitored for 7 years.[90]

The varicella vaccine was introduced for routine use as a single-dose regimen in children 12 months to 12 years of age and showed substantial impact on varicella morbidity and mortality rates in the United States.[98–101] However, active and passive surveillance studies demonstrated that many vaccinated children developed breakthrough varicella after close exposure and could transmit the virus.[102–105] US postlicensure experience led to the recommendation of a two-dose varicella vaccine schedule in 2006, with the first dose given at 12 to 15 months of age and the second dose given at 4 to 6 years of age. The second dose is given to ensure that people who have primary vaccine failure or a limited initial immune response have more complete and persistent protection.[106]

A population-based study of varicella vaccine in Germany in 1- to 4-year-old children found an overall vaccine effectiveness of 87% after one dose and 97% after two doses (the second dose was recommended at least 4 weeks after the first and before 2 years of age), an incremental vaccine effectiveness of two doses of 85%.[107] Catch-up immunization is recommended for children, adolescents, and young adults who previously received only one dose. Children and adults who do not have evidence of VZV immunity should be vaccinated. The criteria for VZV immunity is documentation of two doses of vaccine or birth in the United States before 1980, verification of a history of varicella diagnosed by healthcare personnel, or laboratory evidence of immunity or disease.[69]

Varicella vaccine elicits VZV immunity when administered concurrently with the measles-mumps-rubella (MMR) vaccine and as a quadrivalent measles-mumps-rubella-varicella (MMRV) formulation.[108–110] A single dose of the MMRV vaccine elicited VZV antibody responses in young children that were comparable to those in children who were given a single dose of varicella vaccine; seroconversion rates were approximately 90%.[109,110] A two-dose regimen of the MMRV vaccine was substantially more immunogenic.[109,110]

Postlicensure surveillance showed that young children given the MMRV vaccine were more likely to have fever than those who received MMR and varicella vaccines as separate inoculations (21.5% vs. 14.9%) at the time of their first immunization.[111,112] MMRV vaccine recipients 12 to 23 months of age had a 2.3 times higher relative risk for febrile seizures than those given separate inoculations. These risks of fever and febrile seizures were not observed with the second MMRV vaccine dose. The MMRV vaccine can be given for initial vaccination if after informing parent, the combination is preferred; otherwise MMR and varicella vaccines are given at separate sites. MMRV vaccine is preferred for the second dose.[113]

Two doses of varicella vaccine must be given to susceptible adolescents and adults.[60] Adults are more likely than children to have transient local reactions and rash and to have less persistent VZV antibodies. However, immunization of susceptible adults has important clinical benefit because of their tendency to develop serious varicella and because protection or modified severity of illness is documented despite lower antibody titers.

When it causes skin lesions in healthy recipients, the vaccine virus can be transmitted to susceptible close contacts. In one case, a pregnant woman had generalized cutaneous lesions due to vaccine virus after exposure to a vaccine-related rash in her child. No spread to the fetus was detected.[103]

The Oka-Merck varicella vaccine has been given to children with acute leukemia in remission, reducing the attack rate after household exposure to 13%.[61] Seroconversion in these patients is associated with a high level of protection, but most children required two doses of the vaccine to elicit immunity. A recently published small study of 24 children with a hematologic malignancy and 7 with a solid tumor who received VZV vaccination early during their course of uninterrupted chemotherapy indicated that adaptive immunity, even without seroconversion, could be safely induced.

Varicella vaccination is recommended for children infected with human immunodeficiency virus 1 (HIV-1) with 15% or more $CD4^+$ cells. Sustained protection has been demonstrated in most of these children after two doses of vaccine. The varicella vaccine virus has caused disseminated and chronic infection in children with immunodeficiencies that were not recognized before vaccination.[114–116] Susceptible healthy household contacts should be immunized with varicella vaccine to reduce the risk of household exposure of the high-risk child.[117]

VZV reactivation has been described in a few healthy vaccine recipients,[118] but changes in herpes zoster epidemiology have not been detected as varicella incidence has declined.[119] When the incidence of herpes zoster was assessed among children with leukemia who had vaccine-induced immunity or past natural infection, reactivation was less common after exposure to vaccine virus than wild-type VZV.[120] Because vaccine virus is inhibited by acyclovir, episodes of vaccine-related herpes zoster can be treated with antiviral therapy if necessary. Generalized rashes that occur late after immunization have been caused by breakthrough infections with wild-type VZV.[121] Herpes zoster due to natural VZV can occur after subclinical infection in vaccinated people.[122]

An analysis of medical and other costs related to the annual epidemics of varicella indicates that universal immunization programs directed at healthy children and susceptible adults are cost-effective and safe.[123] Use of varicella vaccine has reduced the incidence of varicella in the United States and other countries.[124] Vaccination also has been associated with reduction of invasive group A streptococcal infections.[125,126] There is limited evidence that suggests that postexposure varicella vaccination of children within 3 days after household contact with a varicella case may reduce the rate and severity of infection.[127]

Herpes zoster vaccine (Zostavax) was licensed in 2006. It is recommended by Advisory Committee on Immunization Practices (ACIP) for prevention of herpes zoster (i.e., shingles) and its complications among adults 60 years or older.[128]

Cytomegalovirus

Robert F. Pass

Cytomegalovirus (CMV) is the most common cause of congenital infection in the United States. Approximately 10% to 20% of affected infants suffer sensorineural hearing loss, ocular damage, or impairment of cognitive or motor function. In addition, CMV is an important opportunistic pathogen in patients with impaired immune function, especially organ transplant recipients, patients with congenital immunodeficiency, and patients with acquired immunodeficiency syndrome (AIDS).

The Virus

Human CMV is a member of the β-herpesvirus group that also includes human herpesvirus (HHV)-6A, HHV-6B, HHV-7, and a large number of related viruses that infect other mammals. Human CMV is a large, complex virus with characteristic morphology and a distinctive focal cytopathic effect in tissue culture. The virus is approximately 200 to 300 nm in diameter; the complete virion is composed of a linear, double-stranded DNA genome within an icosahedral capsid of 162 capsomeres. The capsid is contained within the amorphous tegument comprised mostly of numerous, virus-encoded proteins; the tegument is surrounded by a lipid bilayer envelope derived from the host cell's endoplasmic reticulum–Golgi complex intermediate compartment and containing more than 20 virus-encoded glycoproteins. The genome of human CMV is composed of approximately 235,000 base pairs with 166 protein coding genes.[1] Reiterated terminal and internal base pair sequences divide the genome into unique long (U_L) and unique short (U_S) regions.

Many different cell types are infected by CMV. The virus is able to enter the cell by fusion of specific envelope glycoproteins (gB, gH, gM/gN) with cell surface proteins, including heparan sulfate, cellular integrins, and platelet-derived growth factor-α receptor.[1] CMV also is capable of using an endocytic pathway dependent on proteins from the *UL128, UL130, UL131* gene complex. Viral proteins involved in attachment and entry are important targets for a neutralizing antibody. As with other herpesviruses, synthesis of CMV proteins is directed by sequential transcription of genes. Viral DNA replication, protein synthesis, and assembly of nonenveloped particles take place within the nucleus, where the accumulation of nucleocapsids accounts for the typical “owl's eye” appearance of the intranuclear inclusion. Envelopment of the virus appears to be a multistep process initiated by budding through the nuclear membrane and continued with acquisition of endosomal membranes in the cytoplasm. Virus is transported via the Golgi apparatus to the cell surface for release through exocytosis. The typical cytoplasmic inclusion seen in CMV-infected cells represents the accumulation of nucleocapsids and dense bodies (enveloped tegument without nucleocapsid or DNA) in the Golgi complex.

Pathogenesis

CMV infection in humans involves a complex balance between virus and host, the usual outcome of which is clinically inapparent, persistent infection with establishment of latency. Human CMV encodes numerous genes for proteins that could influence host cell activation, leukocyte movement, inflammatory response, and both innate and adaptive immunity in ways that favor persistence of CMV in the human host.[1,2]

Dissemination, Tissue Tropism, and Persistence

The usual site of inoculation of CMV in a healthy person is a mucosal surface in the upper respiratory or genital tract. Viremia is the likely mechanism for dissemination of CMV to tissues in many different organs, and infection of leukocytes and vascular endothelial cells plays a role. CMV-encoded chemokines, chemokine receptors, and cytokines have the potential to influence the level of viremia by modulating cell trafficking, intracellular signaling, and host cell activation.[1]

Cytopathology caused by CMV often is found in many organs (salivary glands, lung, kidney, liver, pancreas, adrenals, intestinal mucosa), even in people (both healthy individuals and immunocompromised patients) with no premortem evidence of CMV disease. After initial infection the virus is readily isolated from urine, saliva, tears, semen, cervical secretions, and breast milk. On the basis of experience with perinatal, transfusion, and organ transplant transmission of CMV, viral shedding begins around 4 to 6 weeks after acquisition of CMV. Viremia often is detectable at this time and can persist for months, even in a healthy person with asymptomatic infection.[3] Shedding of virus in saliva, urine, and genital secretions typically continues for months to years. Active CMV replication persists in the face of antibody response and the more slowly developing cell-mediated immune response. Viral mechanisms for evading the host's immune response may account for this remarkable persistence. Human CMVs carry multiple genes with the ability to interfere with the host's immune response at different times in the virus replication cycle and by multiple mechanisms.[4–8] Specific functions have been identified that interfere with antigen processing and presentation (trapping or destroying major histocompatibility complex [MHC] class I molecules, degrading MHC class II proteins), impair immune recognition of infected cells, downregulate type I interferon activity, and inhibit natural killer (NK) cell killing. Persistence of CMV in humans is thought to be due to maintenance of the viral genome in stem cells in bone marrow, although persistent replication in epithelial cells of kidney and salivary glands could play a role.[1]

Immune Response

The frequency and severity of disease caused by CMV parallels the extent of impairment of the person's immunity. Patients who are immunocompromised because of chemotherapy, organ transplantation, or AIDS shed CMV from multiple sites, often have persistent viremia, and frequently develop CMV-related disease. Antibody plays an important role in modifying or preventing infection. Infections in transplant recipients who are CMV antibody negative are more likely to be associated with morbidity than infections in patients who are CMV antibody positive before transplantation. Disease from transfusion-acquired CMV infection in small premature neonates almost always occurs in those who lack maternal antibody. Passive and active immunization of seronegative recipients of kidney transplants from seropositive donors reduces the severity of primary CMV infection.[9,10] In addition, immunization with a CMV glycoprotein B (gB) vaccine that stimulated robust antibody responses reduced infection rates in seronegative young women and diminished the impact of infection in patients who had received solid-organ transplants.[11,12] The critical role of cell-mediated immunity in controlling CMV infections is supported by the observation that most severe infections occur in patients with profound impairment of cell-mediated immunity: recipients of solid-organ transplants treated with antithymocyte globulins; recipients of bone marrow transplants; patients with AIDS who have very low numbers of CD4 T lymphocytes; and infants with severe combined immunodeficiency.[13]

Pathogenesis of Congenital Infection

Autopsy studies of fetuses or newborns with congenital infection show that CMV infects numerous cell types and damages multiple organs. A study of 34 fetuses with congenital CMV infection diagnosed in utero reported immunohistochemical detection of CMV in placenta and pancreas specimens from all subjects; lung and kidney each were positive in 87%, liver in 71%, brain in 55%, and heart in 44%.[14] Inflammatory infiltrates were present in CMV-positive organs and correlated with organ damage. Human CMV has been shown to infect neural progenitor cells and impair their growth and differentiation.[15] Brain cells of many different types (nervosa, glia, ependyma, choroid plexus, meninges, vascular endothelium) show cytopathologic lesions and inclusions, but involvement typically is patchy, with focal areas of necrosis. Inclusion-bearing epithelial cells are found in the semicircular canals, vestibular membrane, cochleae, and other structures of the ear.[16,17] Temporal bone anomalies with cochlear, vestibular, and auditory canal defects (Mondini dysplasia) have been associated with deafness in infants with congenital CMV infection. Cytomegalic cells and focal necrosis can be seen in the retina.

Examination of liver specimens reveals periportal lymphoid infiltration, bile stasis, inclusion-bearing cells in bile ducts, giant cell transformation, and necrosis of parenchymal cells.[18] Inclusion-bearing cells without necrosis or inflammatory cell infiltrate usually are found in abundance in glandular epithelial cells (salivary, pancreas, endocrine) and in the lung and kidney. Results with an animal model suggest that CMV damages the developing brain through a number of mechanisms, including lytic infection of cells, interference with neuronal migration, loss of neuronal stem cells, and vascular compromise.[19] In addition to its direct effects on the fetus, CMV impairs fetal development through placental infection, as evidenced by villitis, villous necrosis, and vascular lesions.[20] The predominant placental cell type infected is a fixed connective tissue or stromal cell; CMV also is found in placental macrophages, endothelial cells, and syncytiotrophoblast cells.[21,22] In an in vitro model, CMV infection impaired the ability of cytotrophoblasts to differentiate and invade, suggesting that CMV infection could impair placental function.[23]

Newborns with congenital CMV infection and infants who acquire CMV perinatally do not control the infection as well as adults, shedding virus for much longer periods, sometimes up to years. Developmental immaturity of the immune response to CMV probably contributes to the severity of fetal infection and the inability of infants to control ongoing virus replication. Newborns have reduced antigen-presenting cell (monocytes and dendritic cells) function and reduced NK cell function compared with adults. Fetuses have cellular immune responses to CMV as early as 22 weeks of gestation.[24] A study of mothers with primary CMV infection and their fetuses with congenital infection showed that they had similar levels of activated and memory CD8$^+$ T lymphocytes, but fetuses had lower numbers of PP65-specific (CMV tegument protein) cytotoxic T cells.[25] Newborns with congenital

CMV infection have virus-specific, functional $CD8^+$ T cells that are present in numbers similar to those measured in healthy adults with CMV infection.[26] After in vitro CMV infection myeloid dendritic cells from cord blood produced lower levels of immunomodulatory cytokines than did dendritic cells from adult peripheral blood, deficiencies that could affect T-lymphocyte responses to infection.[27] Impaired lymphocyte proliferative responses to CMV and lower numbers of interferon-γ–producing $CD4^+$ T lymphocytes are found in infants with both congenital and acquired CMV infection.[28,29]

Cytomegalovirus can be transmitted from mother to fetus even if the mother was infected years before conception. In a mother with established immunity, transmission of CMV to the fetus could be the result of reactivation of latent virus or, more commonly, reinfection with new strains. Strong evidence indicates that preconception maternal immunity reduces the risk of congenital CMV infection by threefold to fourfold.[30] Long-term follow-up of children in Europe and North America with congenital CMV infection suggests that sequelae, such as deafness and impaired cognitive function, are more common and more severe when congenital CMV infection is the result of primary gestational infection (Table 206.1).

TABLE 206.1

Sequelae in Children With Congenital Cytomegalovirus Infection by Type of Maternal Infection

Sequela	Primary (% With Sequela)[a]	Recurrence/Reinfection (% With Sequela)[b]
Sensorineural hearing loss	15	5[c]
Bilateral hearing loss	8	0[c]
Speech threshold ≥60 dB[d]	8	0[c]
IQ ≤70	13[e]	0[c,f]
Chorioretinitis	6	2
Other neurological sequelae[g]	6	2
Microcephaly	5	2
Seizures	5	0
Paresis or paralysis	1	0
Any sequel	25	8[c]

[a] Number evaluated equals 112–125 except where noted otherwise.

[b] Number evaluated equals 54–65 except where noted otherwise.

[c] $P \leq 0.05$ for difference between maternal primary and recurrent infection.

[d] For the ear with better hearing.

[e] Number evaluated equals 68.

[f] Number evaluated equals 32.

[g] Four of eight affected children (50%) had more than one abnormality.

Adapted from Fowler KB, Stagno S, Pass RF, et al. The outcome of congenital cytomegalovirus infection in relation to maternal antibody status. N Engl J Med 1992;326:663.

Overall about 35% to 40% of maternal primary infections are transmitted to the fetus. The transmission rate is higher in late gestation infection compared with the early gestation type.[31] However, first trimester maternal infections are more likely to cause congenital infections that are manifest at birth and to be associated with sequelae (retinitis, deafness, mental retardation) than are late gestational infections. Abnormalities (evidenced by prenatal ultrasonography, fetal autopsy, or neonatal examination) were found in 26% of cases when primary maternal infection occurred before 20 weeks of gestation, compared with 6.2% of cases when maternal infection occurred later in gestation.[32] A study of newborns with congenital CMV infection reported that central nervous system (CNS) sequelae occurred in 32% when primary maternal infection occurred in the first trimester, compared with 15% with later gestational infection.[33] A similar study reported hearing loss in 4 of 5 affected infants with first trimester CMV infections; 1 of 12 with second trimester infections; and 0 of 11 with third trimester infections.[34]

Epidemiology

Age-Related Prevalence and Modes of Transmission

Age-related prevalence of CMV infection varies widely, depending on living circumstances and social customs. In areas where the rate of maternal seropositivity is high and breastfeeding is common, more than 50% of all infants acquire CMV during the first year of life. Group care of children facilitates the spread of CMV, especially in toddlers; this leads to a higher prevalence of infection in children attending childcare centers and their caregivers.[35] A seroepidemiologic survey of CMV prevalence based on sera collected from 1988 to 1994 from a random sample of the U.S. population found that the overall prevalence for the United States was 59%.[36] The prevalence was higher in females than males (64% versus 54%), and notably higher in non-Hispanic blacks (76%) and Mexican-Americans (82%) than among non-Hispanic whites (51%). A follow-up report based on sera collected a decade later observed similar rates and reported that CMV seropositivity was independently associated with older age, female sex, foreign birthplace, low household income, household crowding, and low household education.[37] In Africa, Asia, and Latin America, the majority of children are infected by CMV prior to adolescence. Breastfeeding, child-rearing practices, crowding, sanitation, and sexual behavior probably all influence age-related variations in CMV prevalence.

Exposures to young children and sexual contacts are important sources of CMV infection for young women.[38] Young children readily transmit CMV to peers and caregivers, including parents and childcare workers.[35] Oral shedding is common and persists for months or longer; the high frequency of mouthing behaviors in toddlers facilitates transmission of CMV through salivary transfer directly on toys or surfaces or the hands of children and workers. Sexual transmission of CMV is important among adolescents and adults. An early sexual debut, a greater number of partners, nonwhite race, and the presence of other sexually transmitted infections were associated with a higher prevalence of CMV infection among attendees of clinics for treating sexually transmitted infections and among adolescents.[39–41] Restriction enzyme studies of viral DNA provide evidence for transmission of CMV among toddlers and their caregivers in childcare centers, between sex partners, and from child to mother to fetus.[42–44] A population-based study of CMV seropositivity and sexual activity in the U.S. concluded that sexual activity significantly influences rates of CMV infection and that prevention efforts should address this risk.[45]

CMV can be transmitted from mother to offspring transplacentally, at delivery by exposure to virus in the maternal genital tract, and by human milk. Approximately 10% of seropositive mothers shed CMV in the genital tract at delivery, and about 50% of neonates exposed to CMV during birth or from breast milk are infected. CMV can be detected by polymerase chain reaction (PCR) testing in the breast milk of almost all seropositive mothers. Infants who are infected early in life shed virus for years; they are an important source of CMV for other children and caregivers.

Epidemiology of Congenital Infection

Congenital CMV infection is worldwide in distribution; rates range from about 0.3% to 4% of live births.[46] Rates are higher in developing countries and in low-income groups in developed countries. Rates of congenital CMV infection tend to parallel those of maternal seropositivity; populations with a high prevalence of maternal CMV infection also have higher rates of congenital CMV infection. Young maternal age, single marital status, and nonwhite race are associated with higher rates of congenital CMV infection in the United Kingdom and the U.S. Maternal infection with the human immunodeficiency virus (HIV) is a risk factor for congenital CMV infection in some populations in developing countries; lower maternal CD4 counts are associated with greater risk of congenital CMV infection, and antiretroviral prophylaxis reduces the risk.[47–49]

Nosocomial Infection

Most hospital-acquired CMV infections result from transfusions or transplantation. Banked human milk could be a source of infection for newborns. Transfusion-acquired CMV infections in healthy people usually are asymptomatic. Among recipients of bone marrow transplants, blood products, especially leukocytes, can be an important source of CMV infection and disease. The risk of acquiring CMV from blood products is greatest if CMV-seronegative recipients are given multiple transfusions from CMV-seropositive donors. In one study 9.7% of 93 CMV-seronegative children undergoing open heart surgery demonstrated seroconversion; the risk of posttransfusion CMV infection was estimated to be 2.7% per unit.[50] Infection rates of 13.5% and 9.2% were reported in transfused offspring of seronegative mothers in two other studies.[51,52] The risks of infection and disease acquired through transfusion or human milk are increased in neonates with a birth weight less than 1250 g compared with larger infants.[53] Urine, saliva, and other body fluids of CMV-infected patients, especially newborns, often contain high concentrations of virus. Adherence to standard precautions should prevent nosocomial infections from this source.

Occupational Risk of Infection

Nurses, other patient care personnel in hospitals and clinics, childcare workers, schoolteachers, and mothers have frequent close contact with young children; women of childbearing age constitute the majority of individuals in each of these areas. Among hospital workers the risk of CMV infection does not appear to be increased, which suggests that handwashing and other routine precautions in hospitals reduce CMV transmission. In contrast, studies of childcare workers in the U.S. and Canada have shown a consistently higher incidence of CMV infection, with rates from 8% to 20% per year, compared with an expected rate of approximately 2% per year.[35] The risk of acquiring CMV is higher for childcare workers who have contact with younger children.

Clinical Manifestations

Acquired Infections in Healthy People

CMV infection in immunologically normal children and adults usually is asymptomatic, although heterophile antibody-negative mononucleosis is a common manifestation. Clinically, mononucleosis syndrome caused by CMV is indistinguishable from that caused by the Epstein-Barr virus (EBV). Malaise, headache, fever, and fatigue are common among patients with mononucleosis caused by either virus. More than 90% of adults who develop CMV mononucleosis have a fever.[54] High temperatures are common (39°C to 40°C), and the mean duration of fever is longer than 2 weeks. Other clinical findings include pharyngitis, tonsillitis, lymphadenopathy, hepatomegaly, and splenomegaly. A review of clinical findings in 116 immunocompetent adults hospitalized with symptomatic CMV infection reported chills in 39% of patients, sweats in 35%, abdominal pain in 17%, and weight loss in 10%.[55] Rash associated with ampicillin therapy is common with both CMV and EBV mononucleosis.

Elevated serum hepatic transaminase levels occur in more than 90% of patients with CMV mononucleosis; peak alanine transferase levels rarely are higher than 300 mIU/mL. Elevation of the bilirubin level above 2 mg/dL occurs in less than 5% of patients. Lymphocytosis with atypical lymphocytes (usually 10% to 35%) occurs consistently. Children with CMV mononucleosis are less likely than adults to have fever (43% versus 94%) but are more likely to have hepatomegaly (100% versus 53%) and splenomegaly (86% versus 53%).[56] The expected outcome of CMV mononucleosis in healthy people, including those with transfusion-acquired infection, is recovery without sequelae. However, symptoms can persist for 4 weeks or longer. A laboratory-based study that identified 124 immunocompetent, symptomatic adults with serologic evidence of recent CMV infection reported that symptoms persisted for an average of 7.8 weeks.[57]

Severe illness caused by CMV infection in healthy people has been described in a small number of patients. Complications infrequently associated with CMV infection in a healthy person include venous thromboembolism, uveitis with iris atrophy, persistent thrombocytopenia, hemolytic anemia, myocarditis, gastrointestinal ulceration, transverse myelitis, Guillain-Barré syndrome, and encephalitis.[1] A review of 21 healthy people with encephalitis attributed to CMV infection found that the patients presented with confusion, coma, seizures, aphasia, dysphasia, and cranial nerve abnormalities; recovery was slow, and some patients had persistent abnormalities.[58] Severe CMV infection in a health person is sufficiently uncommon that when it is suspected, a careful evaluation of the patient's immunocompetence is warranted.

Congenital Infection

The clinical manifestations of congenital CMV infection can be divided into findings in the neonate and signs of CNS damage that usually are not fully apparent until later in childhood. More than 90% of neonates with congenital CMV infection appear healthy at birth. A study of 267 cases of congenital CMV infection, identified by virologic screening of more than 27,000 neonates, found that 7% of infected subjects had petechiae, hepatosplenomegaly, microcephaly, thrombocytopenia, or jaundice with conjugated hyperbilirubinemia, and the remainder had no signs of congenital infection at birth.[59]

Clinical and laboratory findings for 106 neonates with symptomatic congenital CMV infection are summarized in Tables 206.2 and 206.3. Symptomatic congenital CMV infection portends significant morbidity; 13 of 106 (12%) of the affected infants died by 6 weeks of age, and the mean duration of hospitalization was 16 days.[60] Evidence of CNS involvement (microcephaly, lethargy-hypotonia, poor suck, seizures, optic atrophy, decreased hearing sensitivity, or intracranial calcifications) is present in approximately two thirds of symptomatic neonates.[60,61] Infants with symptomatic congenital CMV infection at birth are likely to have CNS and sensory impairments, including mental retardation, cerebral palsy, sensorineural hearing loss, and vision loss.

TABLE 206.2

Newborn Clinical Findings in 106 Infants With Congenital Cytomegalovirus Infection Who Were Symptomatic at Birth

Abnormality	%[a]
Prematurity[b]	34
Small for gestational age[c]	50
Reticuloendothelial abnormality (one or more of the following):	
Petechiae	76
Jaundice	67
Hepatosplenomegaly	60
Purpura	13
Neurological abnormality (one or more of the following):	68
Microcephaly[d]	53
Lethargy/hypotonia	27
Poor suck	19
Seizures	7

[a] Number evaluated equals 102–106.

[b] Gestational age <38 weeks.

[c] Weight <10th percentile for gestational age.

[d] Head circumference <10th percentile based on Colorado Intrauterine Growth Charts for premature newborns.

TABLE 206.3

Laboratory Abnormalities in 106 Infants With Congenital Cytomegalovirus Infection Who Were Symptomatic at Birth

Test	Abnormal/Total Examined (%)
Elevated ALT (>80 units/L)	46/58 (83)
Thrombocytopenia	
<100,000/mm^3	62/81 (77)
<50,000/mm^3	43/81 (53)
Conjugated hyperbilirubinemia	
Direct serum bilirubin >2 mg/dL	55/68 (81)
Direct serum bilirubin >4 mg/dL	47/68 (69)
Hemolysis	37/72 (51)
Increased cerebrospinal fluid protein (>120 mg/dL)[a]	24/52 (46)

[a] Determinations made in the first week of life.

From Boppana SB, Pass RF, Britt WJ, et al. Symptomatic congenital cytomegalovirus infection: neonatal morbidity and mortality. Pediatr Infect Dis J 1992;11:93.

A review of 15 studies that screened infants for congenital CMV infection reported that 40% to 58% of symptomatic newborns and 13.5% of those without symptoms at birth had permanent sequelae, with the caveat that these likely are underestimates.[62] Neonates with symptomatic congenital CMV infection should be considered at high risk for sequelae, even if clinical findings are mild. Chorioretinitis, microcephaly, and neurological abnormalities are associated with an increased risk of mental retardation. Computed tomography, ultrasound, and magnetic resonance imaging techniques can provide evidence of CNS involvement in newborns with congenital CMV infection, and abnormal imaging results are predictive of CNS sequelae.[63,64] Abnormalities noted in patients with symptomatic congenital CMV infection include periventricular calcifications, lenticulostriate vasculopathy, periventricular cysts, ventricular dilatation, cortical atrophy, cerebellar hypoplasia, polymicrogyria, and lissencephaly. CNS imaging usually is performed only in newborns with signs of congenital infection; however, CNS abnormalities have been found in a small number of newborns in whom the virus was detected by virologic screening, but who had no signs of congenital infection. Ultrasonography has been recommended as the initial neuroimaging study.[63] It does not require sedation or involve exposure to radiation, and ultrasound findings have correlated with outcome.

In contrast to the high rate of CNS impairments among infants with symptomatic congenital CMV infection, most infected newborns with no clinical abnormalities at birth remain free of sequelae. However, infants with asymptomatic congenital CMV infection have higher than expected rates of sensorineural hearing loss, which is similar in severity and clinical course to hearing loss in symptomatic patients. Congenital CMV infection is a leading cause of sensorineural deafness and of mental retardation in children.

Hearing loss caused by congenital CMV infection often is progressive during childhood. Children with normal hearing at birth can develop hearing loss later, and a high proportion of infants with hearing loss experience further decline in hearing sensitivity. Late onset or progressive hearing loss usually occurs during the first 2 years of life, but decline in hearing sensitivity has been observed in school-aged children with congenital CMV infection. Retinitis also can reactivate, leading to further impairment of vision. Little evidence exists for postnatal progression of brain lesions, but this possibility has received insufficient study.

Acquired Infection in Premature Newborns

Transfusion-acquired CMV infection in premature newborns can produce a clinical syndrome of hepatosplenomegaly, atypical lymphocytosis, thrombocytopenia, worsening of respiratory status, and a septic appearance. The risk of CMV infection and disease is related to a very low birth weight (<1250 g), exposure to multiple units of blood, and birth to a seronegative mother. Fortunately, transfusion-acquired CMV infection in newborns is now prevented by limiting transfusion to seronegative donors or blood that has been filtered through cotton wool to remove leukocytes. However, some small premature newborns acquire CMV from a maternal source (e.g., maternal milk) and develop clinical syndromes similar to those observed with transfusion-acquired infection. Postnatal CMV infection was found in 59% of newborns of less than 32 weeks' gestation and less than 1500 g birth weight who were fed mother's milk that tested CMV positive.[65] The onset of CMV infection was accompanied by symptoms in approximately half of patients. A sepsislike syndrome (apnea, bradycardia, gray pallor, bowel distention), with onset of infection during the first 2 months after birth, occurred in some of the more premature newborns. Laboratory abnormalities, including leukopenia, thrombocytopenia, abnormal serum hepatic enzymes, and elevated C-reactive protein, have been observed.[65,66] Compared with term infants small premature newborns have lower levels of transplacentally acquired maternal CMV immunoglobulin G (IgG), and their levels of antibody can decline rapidly after birth as a result of repeated blood sampling. Although early postnatal acquisition of CMV infection in small premature newborns has been associated with CNS sequelae, the impact is controversial.[67] Because of the established benefits of mother's milk in preterm infants, there is no consensus on steps that should be taken to prevent or treat CMV infection transmitted from mother to very low birth weight premature newborns.[68]

Cytomegalovirus in Solid-Organ Transplantation

When either the donor or the recipient of an organ is seropositive, CMV infection occurs in 50% to 100% of patients after immunosuppression and transplantation. The principal sources of infection are reactivation of endogenous latent virus, the transplanted organ or tissue, and transfusion of untreated blood from seropositive donors. Disease attributed to CMV is most common among seronegative recipients of solid organs or tissue from seropositive donors, although immunosuppression can lead to severe disease in transplant recipients who are CMV seropositive before transplantation. Before the use of antiviral agents to prevent CMV disease became widespread, CMV disease occurred in most CMV-seronegative solid-organ transplant (SOT) recipients who received organs from CMV-seropositive donors (D^+/R^-) and in approximately 5% to 25% of CMV-seropositive recipients. CMV disease substantially increases the duration and costs of hospitalization for SOT recipients.

The onset of viremia, virus shedding, and CMV disease usually occurs 4 to 12 weeks after transplantation. The hallmarks of CMV disease in SOT recipients are fever, malaise, arthralgia, leukopenia or pancytopenia, and laboratory evidence of hepatitis. More serious consequences of CMV infection include pneumonitis, retinitis, and gastrointestinal ulceration. Indirect effects attributed to CMV infection include coinfection with opportunistic pathogens (e.g., *Pneumocystis jirovecii, Aspergillus* spp.), and deterioration of graft function. Primary CMV infection in renal transplant recipients is associated with graft rejection or acute glomerular injury. Persistent hepatitis and hepatic failure are associated with CMV infection in liver transplant recipients. Pneumonitis is more common in patients infected with CMV who have received lung or heart-lung transplants. Accelerated development of coronary artery atherosclerosis has been associated with CMV infection in cardiac transplant recipients. Rates of CMV disease vary widely among transplant centers. Risk factors for greater severity of CMV infection in SOT recipients include primary infection, intensive T-lymphocyte suppressive regimens, and high levels of viremia. Recent reviews provide detailed discussions of the clinical manifestations, diagnosis, prevention, preemptive therapy, and management of CMV infection in SOTs.[69–71]

Cytomegalovirus in Hematopoietic Stem Cell Transplantation

The sources of CMV among recipients of a hematopoietic stem cell transplant (HSCT) are similar to those among SOT recipients. The CMV syndrome (fever, malaise, leukopenia, hepatitis) that sometimes accompanies the onset of CMV infection in SOT patients also can occur in HSCT patients. The two most troublesome manifestations of CMV disease in HSCT patients are pneumonitis and gastrointestinal disease. Before antiviral agents were used routinely to prevent CMV disease in HSCT patients, interstitial pneumonia caused by CMV was common and the mortality was high in affected patients. A 1996 review of CMV disease among patients receiving allogeneic HSCT over a 20-year period found that in 8.6% of transplantations in which either the donor or the recipient was CMV positive before the procedure, the recipient developed CMV disease.[72] Among patients with CMV disease, 64% had pneumonitis alone, 18% had gastrointestinal disease alone, and

9% had pneumonitis plus gastrointestinal disease; there was one case each of retinitis, hepatitis, and encephalitis. Analysis of factors related to outcome of CMV pneumonia among HSCT patients reported survival at 6 months of 30%; lymphopenia and a need for mechanical ventilation were associated with increased mortality, and treatment with ganciclovir or foscarnet was associated with improved outcome.[73] Indirect effects of CMV disease in HSCT patients include greater frequency of opportunistic bacterial and fungal infections and possibly greater all-cause mortality. Factors associated with an increased risk of CMV disease among HSCT patients include D^+/R^- transplants, donor-recipient histoincompatibility, myeloablative conditioning regimens, graft-versus-host disease, and immunosuppressive regimens that induce lymphopenia or profound impairment of T lymphocytes (high-dose corticosteroids, mycophenolate mofetil, T-lymphocyte depletion, anti-CD52 or antithymocyte globulin).[74]

Prevention of CMV disease in D^+ or R^+ HSCT patients during the first 90 to 120 days after transplantation, largely by the use of antiviral agents, has reduced the rate of CMV disease during this period. However, late onset CMV disease remains a problem. Among HSCT patients who received either prophylactic or preemptive antiviral therapy to prevent CMV disease in the first 100 days after transplantation, 18% experienced late onset CMV disease, at an average of 5.5 months after the procedure.[75]

Cytomegalovirus in HIV Infection

Treatment with combination antiretroviral therapy (ART) has significantly reduced the occurrence of CMV disease among adults and children with HIV or AIDS. Most CMV disease in adults with AIDS occurs in those with extremely low CD4 lymphocyte counts (usually $<50/\text{mm}^3$). The most common manifestations of CMV disease in adults with AIDS are retinitis, esophagitis, colitis, or some combination of these. Encephalitis, peripheral neuropathy, polyradiculoneuritis, pneumonitis, gastritis, hepatitis, adrenalitis, skin lesions, oral mucosal ulceration, and sialoadenitis are less common. CMV disease has similar manifestations in children with HIV. In HIV-infected infants, CMV disease is not as strongly associated with profoundly low CD4 counts as it is in adults. Before control of HIV infection was achieved with antiretroviral drugs, coinfection with CMV was associated with more rapid progression to AIDS.[76] Data from the Perinatal AIDS Collaborative Transmission Study showed a more than 10-fold reduction in nonocular CMV disease and a similar dramatic reduction in retinitis in the era of ART compared with pre-ART days.[77] Now CMV disease rarely is encountered in children with HIV infection living in the U.S. The rate of congenital CMV infection in HIV-uninfected infants born to HIV-infected mothers also has decreased from 3.5% to 1.2% in the era of ART, according to data from the French Perinatal Cohort.[78]

Laboratory Diagnosis

Serologic Tests.

Although serologic methods are of limited value for diagnosis of CMV infection in immunocompromised patients, they are used widely for screening and to provide the basis for distinguishing primary infection from past infection in a healthy person (Box 206.1). Enzyme immunoassays are commonly used to detect both IgG and IgM antibodies to CMV.

Box 206.1

Clinical Uses of Cytomegalovirus Serology

CMV IgG

Screening to determine whether subject ever has been infected

- Blood and organ donors
- Organ transplant candidates
- Immunocompromised patients
- Pregnant women

Detection of seroconversion from Cytomegalovirus (CMV) IgG negative to CMV IgG positive, proving primary infection

CMV IgM

Testing for recent CMV infection in an immunocompetent patient with a compatible illness

Testing of pregnant women for primary CMV infection, using CMV IgG avidity testing for confirmation

Not useful in immunocompromised patients

Not recommended for diagnosis of congenital infection

Serum IgG antibody to CMV is used to screen for past CMV infection, so as to determine several risks: the risk of virus transmission (blood and organ donors); the risk of reactivation disease in immunocompromised patients; and the risk of acquiring the virus for those likely to be exposed. Although CMV IgM antibody assays are widely used to detect primary infection, they vary in accuracy for this purpose. Demonstration of low-avidity CMV IgG antibody testing improves the specificity of a positive CMV IgM test result.

Diagnosis of Congenital Infection.

The diagnosis of congenital CMV infection is confirmed by detection of the virus in body fluids within the first 3 weeks of life. Urine and saliva are the preferred specimens for testing. CMV can be detected easily in the urine of newborns with congenital infection by its characteristic cytopathic effect in tissue culture, or by rapid, centrifugation-enhanced (shell vial) culture using monoclonal antibody to early antigens. However, currently PCR and real-time PCR have advantages in sensitivity, rapid turnaround time and potential for automation and are used widely. A prenatal diagnosis of fetal infection is made by detection of CMV in amniotic fluid.

After 3 weeks of age excretion of CMV could be the result of acquisition of the virus during birth or through breast milk. Serologic methods should not be used for diagnosis of congenital CMV infection. Higher levels of CMV in the blood, as measured by quantitative competitive or real-time PCR, have been associated with an increased risk of hearing loss and other sequelae. However, a threshold quantity of CMV in the blood or urine that can be used as a basis for management of newborns with congenital infection has not been established.

Diagnosis in Immunocompromised Patients.

The detection of CMV in body fluids or tissues of immunocompromised people does not prove that clinical findings are related to CMV. However, because primary CMV infection commonly causes disease, the development of antibodies to CMV or documentation of viremia or viral excretion in a previously seronegative patient provides strong support for a causal role. In transplant recipients with primary CMV infection, viremia, virus excretion, seroconversion, and clinical abnormalities usually occur 4 to 12 weeks after transplantation. In immunocompromised patients with reactivated CMV infection, neither antibody response nor excretion of virus in urine, saliva, or respiratory tract secretions is a reliable indicator of CMV disease.

In both SOT and HSCT management, all donors and recipients should be tested for CMV IgG antibody before transplantation to identify patients who are at risk for primary infection and those likely to experience reactivation after immunosuppression. After transplantation the most widely used laboratory tests to identify patients with or at risk for CMV disease are assays that estimate the quantity of virus in the blood. A number of assays have been used for this purpose: antigenemia (quantitation of white blood cells [WBCs] positive for CMV PP65), assays that amplify virus-specific messenger ribonucleic acid (mRNA), antigen capture with monoclonal antibody, quantitative competitive PCR, and real-time PCR. The quantity of CMV DNA in blood predictive of disease varies with the method of measurement, the type of sample (whole blood, plasma, leukocytes), and the clinical setting. Real-time PCR of plasma or whole blood now is used widely because of its sensitivity, ability to quantify viral DNA in clinical specimens over a wide range of concentrations, and adaptability to automation. A World Health Organization (WHO) International Standard for human cytomegalovirus (HCMV) DNA is available; calibrating secondary standards for commercial and laboratory-based assays on clinical samples should make it possible to achieve interlaboratory consistency in quantitative results. However, significant differences in quantitative results can occur between laboratories using the WHO standard and with secondary standards, probably as a result of laboratory-specific variability in DNA extraction and other testing procedures.[79] The lack of standardization in laboratory assays and the fact that the level of CMV in blood that predicts disease varies with the clinical setting make it difficult to establish recommendations on cutpoint levels for clinical significance.

Treatment

Treatment of CMV mononucleosis is not indicated for an immunocompetent person because the illness is expected to resolve without sequelae. In rare cases of severe or life-threatening disease in an immunocompetent person, a thorough evaluation of immune function should be performed, and the infection reasonably can be managed the same way as infection in an immunodeficient person.

Congenital Infection.

Antiviral treatment of newborns with symptomatic congenital CMV infection is recommended to improve hearing and developmental outcome.[80] Valganciclovir (mono-valyl ester of ganciclovir) given orally is recommended (16 mg/kg/dose twice daily for 6 months).[81] Ganciclovir given intravenously (6 mg/kg/dose every 12 hours) can be substituted if the patient is unable to take oral medications. Treatment is associated with neutropenia, which is reversible with dosage adjustment or discontinuation of the medication. Animal studies indicate the potential for reproductive toxicity and carcinogenicity at levels similar to those achieved in treating humans, but similar toxicity has not been reported in humans. Most newborns with congenital CMV infection have no clinical evidence of CMV disease in the first month of life and will not develop hearing loss or other sequelae. Neither screening for the virus at birth nor antiviral treatment of asymptomatic neonates is recommended at this time because the evidence is insufficient to allow a risk-versus-benefit assessment.

Infection in Immunocompromised Patients.

Detailed guidelines for preventing and treating opportunistic infections, including CMV, in HIV-infected adults and adolescents can be found at the AIDSinfo website (http://aidsinfo.nih.gov).[82] A separate guideline for children is available on the website.[83] Key points from these evidence-based guidelines are summarized here. Preventing CMV disease is best achieved by maintaining patients on effective ART and achieving a CD4 count higher than 100 cells/mm^3 for adults, adolescents, and children 6 years of age or older; and, for children younger than 6 years, a CD4 percent greater than 10%. Annual CMV antibody testing is recommended beginning at 1 year for HIV-infected children who are initially CMV seronegative and have not exceeded these CD4 cell thresholds.

Antiviral treatment to prevent CMV disease is recommended for HIV-infected adults, adolescents, and children 6 years or older who are CMV seropositive and whose CD4$^+$ cell counts are lower than 50 cells/mm^3; for children younger than age 6 years, a CD4 percentage below 5% is the threshold for prophylaxis. Oral valganciclovir is recommended for preventive treatment under these circumstances. Patients should be taught the importance of recognizing visual symptoms and performing regular eye examinations so that CMV retinitis can be detected and treated promptly. In HIV-infected patients, CMV retinitis and other end-organ disease are treated with ganciclovir intravenously or valganciclovir orally. Foscarnet is the preferred alternative if viral resistance to ganciclovir is detected. After active disease has been controlled, patients are continued on maintenance antiviral therapy until immune reconstitution is achieved. Maintenance therapy is not recommended for patients with disease limited to the lungs or gastrointestinal system. Combination antiviral therapy with ganciclovir and foscarnet should be considered for patients with CMV CNS disease, resistance to ganciclovir, or failure to respond to monotherapy. Although guidelines are detailed and updated regularly, consultation with a specialist experienced in the prevention and treatment of CMV infections is recommended.

Prevention and Treatment of CMV Infection in Patients Who Have Received Transplants.

Consensus guidelines and literature reviews of published studies on approaches to the prevention and treatment of CMV disease in

SOT and HSCT patients are helpful, but consultation with an expert in the management of CMV infections in these patients is recommended.[84–86] Most guidelines endorse the use of antiviral agents to prevent or treat CMV disease in SOT recipients, with the possible exception of those who are CMV seropositive before transplantation and are perceived to be at low risk of CMV disease based on donor match, immunosuppressive regimen, and type of transplant.[84–86] All D^+/R^- SOT patients require an approach to prevent CMV disease, as do R^+ patients, especially those at greater risk of severe disease because of an immunosuppressive regimen or the type of transplant (e.g., heart-lung). Antiviral prophylaxis (usually with oral valganciclovir) is used for high-risk patients (i.e., D^+/R^- recipients) and when the donor or recipient is CMV positive and T-cell depletion is used. The duration of prophylaxis can vary from 100 days to a full year. In a preemptive approach recommended for lower risk patients (i.e., those not treated with T-cell depleting antibodies), the CMV viral load in the blood is monitored regularly, and antiviral therapy is initiated when a threshold viral load is reached.[84]

Antiviral prophylaxis has the disadvantage of exposing many patients to antiviral agents who would not develop CMV disease, and it could increase the prevalence of drug-resistant virus. In addition, late onset disease (after the antiviral agent has been discontinued) seems to occur more frequently in patients given prophylaxis than in those managed with a preemptive approach. The preemptive strategy has the advantage of reducing antiviral use substantially, but it requires a laboratory capable of providing frequent viral load results (weekly or more often) for months. CMV immune globulin (CMV-IG) is used commonly in SOTs as part of a prophylactic regimen for preventing CMV disease. A multicenter, randomized, placebo-controlled clinical trial of CMV-IG in D^+/R^- renal transplant patients in the 1980s showed a statistically significant reduction in CMV disease and opportunistic fungal and parasitic infections among treated patients compared with placebo controls, although the rate of CMV infection was not reduced.[10] A 2007 Cochrane review examined published randomized trials in SOT patients comparing CMV-IG or standard immune globulin intravenous (IGIV) with placebo and with no treatment.[87] No difference in outcome was found between patients receiving CMV-

IG or IGIV compared with those receiving a placebo or no treatment. Transplantations in which the donor and recipient are CMV seronegative pose little or no risk of CMV disease. Assuming that steps are taken to prevent infection through blood products, D^-/R^- transplants do not need a preventive antiviral regimen.

Intravenous ganciclovir is the preferred antiviral agent for treatment of CMV disease in transplant recipients, although oral valganciclovir can be used if the patient is not seriously ill and can take medication. Antiviral treatment is continued until clinical and laboratory abnormalities related to CMV infection show substantial improvement and the viral load declines (usually in 14 to 21 days). If the viral load is used to assess the effectiveness of treatment, antiviral therapy usually is continued until the quantity of virus in the blood drops below the threshold that would trigger initiation of treatment. Failure to clear viremia has been associated with recurrence of CMV disease. After initial control of the CMV infection has been achieved, maintenance therapy with oral valganciclovir is used to prevent recurrence. Foscarnet alone or with ganciclovir can be used as an alternate agent if CMV is resistant to ganciclovir, ganciclovir is not tolerated, or the patient fails to respond to treatment.

Guidelines for prevention of opportunistic infections in HSCT patients and protocols from leading HSCT centers are good sources of information on preventing and treating CMV infection.[88–90] A CMV disease prevention program should be used for all R^+ and all D^+/R^- HSCT patients from the time of engraftment until 100 days after transplantation. Either prophylactic or preemptive treatment with intravenous ganciclovir is recommended for recipients of allogeneic hematopoietic cells; foscarnet is an alternative agent for prophylaxis. Oral valganciclovir now is widely used in place of intravenous ganciclovir. Blood products from seronegative donors or leukocyte-reduced, filtered blood should be used for CMV-seronegative HSCT patients to prevent infection from transfused blood products. Randomized, placebo-controlled clinical trials in seronegative recipients of allogeneic stem cells have failed to show efficacy of CMV-IG for preventing CMV disease, and CMV-IG currently is not recommended for prophylaxis.[91,92]

Although autologous HSCT recipients are considered low risk for CMV disease, weekly viral load monitoring for 60 days after transplantation is recommended for CMV-seropositive HSCT recipients who have underlying hematologic malignancies or receive intense immunosuppressive regimens. CMV viremia is associated with an increased risk of overall mortality in the first year after transplantation.[93] About 8% to 10% of CMV-seropositive HSCT patients develop CMV disease in the first year after transplantation. Treatment of CMV disease in HSCT patients is similar to the approach used in SOT patients. Induction treatment is given for 2 to 3 weeks, followed by maintenance therapy for weeks to months. Treatment is initiated with intravenous ganciclovir (or foscarnet); transition to valganciclovir can be considered after substantial improvement has been achieved, assuming the patient can take medications. The duration of maintenance therapy is longer for patients recovering from CMV pneumonia and in those in whom immunosuppression could not be reduced. Although the protocol is controversial, some centers use CMV-IG or IGIV in addition to antiviral therapy in HSCT patients to treat CMV pneumonia.

Cytomegalovirus Antiviral Drug Resistance.

CMV resistance to antiviral agents is encountered when prolonged treatment is required and ongoing viral replication cannot be suppressed effectively. Relatively high rates of CMV resistance to ganciclovir were common in adult patients with AIDS in the pre-ART era. Transplant patients often require prolonged courses of antivirals to treat CMV infection, and rates of antiviral drug resistance of 5% to 10% have been reported (higher rates are associated with more severe CMV disease).[94] Antiviral drug resistance should be suspected in patients with CMV disease who are not improving clinically on treatment and who do not show a decrease in the viral load of blood or plasma. Three currently licensed CMV antiviral agents (ganciclovir/valganciclovir, foscarnet, and cidofovir) all act on the viral DNA polymerase. Ganciclovir requires phosphorylation by a viral kinase before it can complete phosphorylation by cellular kinases. Mutations in the CMV gene, *UL97*, that encodes the viral kinase, and mutations in the viral DNA polymerase gene, *UL54*, can lead to ganciclovir resistance. Resistance to foscarnet and cidofovir is mediated by mutations in the DNA polymerase gene. Genotypic testing for resistance mutations is available from specialty laboratories.

Management of patients in whom antiviral resistance is suspected or proven is challenging because these usually are patients who are severely immunocompromised, have high levels of CMV in the blood despite treatment, and have uncontrolled CMV disease. Their management should include consideration of modification of immunosuppressive regimens, in addition to an alternative antiviral regimen. Depending on the results of genotypic resistance testing, an advantageous approach might be to increase the dose of ganciclovir to overcome *UL97* mutations that confer low-level resistance; to change to foscarnet; or to use combination therapy. If ganciclovir resistance is due to *UL54* mutations, resistance to cidofovir also is likely. For a more detailed discussion of this topic, the reader should study a review of the biology and clinical significance of CMV antiviral resistance.[94]

Prevention

Transmission of CMV appears to require direct contact with infected body fluids. The two leading sources of community-acquired CMV infection are contact with young children and intimate contact. Prevention of these exposures is challenging because they are a normal part of family and social life and child rearing. Because CMV infection in a healthy person almost always is silent clinically, it is prudent to assume that contact with saliva, urine, or other body fluids from anyone is a potential source of CMV.

Prevention of Maternal and Congenital Infection.

Handwashing and following Standard Precautions are recommended to prevent CMV infection in pregnant women and in those who care for infants and children.[95,96] Specific steps that can be taken by pregnant women (and others) to avoid exposure to body fluids that might contain CMV are presented in (Box 206.2).

Box 206.2

Centers for Disease Control Recommendations for Pregnant Women to Reduce Exposure to Cytomegalovirus and

the Risk of Fetal Infection

Wash your hands often with soap and water for 15 to 20 seconds, especially after:

- Changing diapers
- Feeding a young child
- Wiping a young child's nose or drool
- Handling children's toys

Do not share food, drinks, or eating utensils used by young children

Do not put a child's pacifier in your mouth

Do not share a toothbrush with a young child

Avoid contact with saliva when kissing a child

Clean toys, countertops, and other surfaces that come into contact with children's urine or saliva

Studies in pregnant women suggest that providing them with information on the risks of CMV, in addition to clear steps for prevention, results in reduced rates of infection during pregnancy.[97,98] Most primary CMV infections in pregnant women go unrecognized because they are asymptomatic. Prenatal screening for CMV infection currently is not recommended. CMV immune globulin treatment of pregnant women with primary CMV infection has been studied as a means of preventing transmission to the fetus and improving the outcome for infected fetuses.[99–101] The only randomized, observer-blind clinical trial performed thus far reported no statistically significant reduction in the rate of fetal infection or the outcome of fetal infection among babies born to women who received CMV-IG; however, because of the study's limited sample size and power, a modest treatment effect could not be excluded.[101] A larger phase 3 clinical trial in mothers with primary gestational CMV infection currently is testing the efficacy of CMV-IG treatment for preventing congenital infection.[102]

Prevention of Healthcare-Acquired Infection.

Nosocomial CMV infections that occur by transmission between patients and healthcare workers are rare, probably because of the handwashing and body fluid precautions that are part of routine hospital care. Transfusion-acquired CMV infections can be prevented either by filtering blood to remove WBCs or by screening donors so that only seronegative blood products are provided to seronegative high-risk patients. However, these two strategies are not equally effective for high-risk HSCT patients; some unexpected CMV infections still occur in patients receiving filtered blood products.[103]

CMV potentially can be transmitted through assisted reproductive technology. The American Society for Reproductive Medicine has published guidelines for screening sperm and oocyte donors, and for preventing CMV infection in recipients.[104,105]

Cytomegalovirus Vaccine.

Currently no vaccine for preventing CMV infection and disease has won the approval of the U.S. Food and Drug Administration. The Towne strain live-attenuated CMV vaccine showed limited efficacy for preventing severe disease in renal transplant recipients, but vaccination did not prevent infection either in transplant recipients or in healthy adults exposed to young children shedding CMV.[9,106] The results of phase 2 randomized, placebo-controlled clinical trials of a recombinant, subunit CMV vaccine based on the envelope glycoprotein gB are encouraging. This vaccine achieved 50% efficacy for prevention of maternal infection in high-risk young women.[12] In addition, pretransplant immunization with the CMV gB vaccine improved control of CMV infection in SOT patients.[11] Another phase 2 randomized, placebo-controlled clinical trial, involving a therapeutic DNA vaccine with plasmids encoding CMV glycoprotein B and PP65, was conducted in CMV-seropositive HSCT patients; vaccination decreased the occurrence of clinically significant viremia.[107] A number of other CMV vaccines are in development, but it is unlikely that any will be licensed in the next few years.

Key Points

Cytomegalovirus Infections

Virology

- Large, complex virus, member of herpesvirus family
- Double-stranded DNA with about 160 open reading frames
- Much of genome devoted to immune evasion or interaction with host's immune functions
- Persists in latent form indefinitely

Epidemiology

- Endemic in all human populations
- Prevalence increases with age but varies depending on child-rearing and other practices.
- Perinatal transmission is an important epidemiologic feature.
- Transmission of CMV primarily is by direct contact with body fluids.
- CMV is shed in body fluids for months to years after primary infection.
- Transplacental transmission infects about 0.7% of fetuses worldwide.

Clinical Features

- Almost all postnatal infections in normal infants are clinically silent.
- CMV rarely causes a mononucleosis syndrome.

- Approximately 10% of newborns with fetal infections show typical signs of congenital infection at birth.

- Congenital infection is a leading cause of hearing loss and CNS impairments.

- CMV is a major cause of morbidity in immunocompromised patients.

Diagnosis

- Serum IgG antibody identifies patients who have ever been infected.

- Congenital infection is diagnosed by detection of the virus in body fluids before 3 weeks of age.

- Quantity of virus in body fluids is used to identify immunocompromised patients at risk for disease.

Prevention

- Specific measures are used to prevent disease in immunocompromised patients.

- Specific measures are recommended for avoiding exposure during pregnancy.

Treatment and Chemoprophylaxis

- Newborns with symptomatic congenital CMV infection likely will benefit from antiviral treatment.

- Antiviral chemoprophylaxis is used to prevent CMV disease in certain immunocompromised patients.

- CMV disease in immunocompromised patients is treated with antiviral agents.

- Immunocompromised patients who develop CMV disease may require maintenance antiviral treatment to prevent recurrent disease.

Human Herpesviruses 6 and 7 (Roseola, Exanthem Subitum)

Mary T. Caserta

Human Herpesvirus 6

Human herpesvirus 6 (HHV-6) was first isolated from the peripheral blood lymphocytes of adults with lymphoproliferative diseases and human immunodeficiency virus (HIV) infection and was named human B-lymphotropic virus.[1] When additional isolates were identified in CD4$^+$ lymphocytes, further characterization indicated that the virus was a herpesvirus. Because it was the sixth member of the herpesvirus family, it was renamed *Human herpesvirus 6*. Two years after its initial isolation, HHV-6 was discovered in the lymphocytes of four infants with roseola.[2] Subsequently, HHV-6 was established as the prime cause of this common illness of the young, which for many decades was prophetically known as “the sixth exanthematous disease of childhood.” HHV-6 is an important pathogen in young children globally, and as is characteristic of herpesviruses, it subsequently establishes persistent, latent, and lifelong infection.

Description of the Pathogen

HHV-6A, HHV-6B, and HHV-7 comprise the *Roseolovirus* genus of the subfamily β-Herpesvirinae. They have the characteristic human herpesvirus family's morphology and structure: an electron-dense nucleic acid core encased in an icosahedral capsid surrounded by proteins collectively known as the tegument, and an outer envelope containing proteins and glycoproteins in a lipid bilayer. The linear, double-stranded deoxyribonucleic acid (DNA) genome of HHV-6 is 160 to 170 kilobases (kb) and has a unique central region (U), which contains open reading frames (ORFs) U1–U100 bounded on each end by terminal direct repeats (tDR). HHV-6A, HHV-6B and HHV-7 all share limited homology with human cytomegalovirus (CMV), the only other human β-herpesvirus.[3,4] The overall nucleotide sequence identity between HHV-6A and HHV-6B is approximately 90%, but less in the direct repeats (85%) and U86–U100 (72%).[5,6] HHV-6A and HHV-6B are colinear with minimal (<1%) intragroup variation.[3] Although HHV-6A and HHV-6B initially were classified as separate subgroups of HHV-6, in 2012 the two were recognized officially as distinct species based on differences in biology, immunology, epidemiology, and disease associations.[7]

HHV-6B causes almost all primary infections in infants and is the predominant virus associated with reactivated infection in immunocompetent and immunocompromised individuals.[3,7] However, in a previous report from an African population, most of the infant infections were associated with HHV-6A.[8] More recent data have not confirmed this finding.[9] HHV-6 infects mature T lymphocytes in vitro, especially activated CD4$^+$ cells. However, in contrast to the findings of the in vitro studies, HHV-6B replicates more efficiently in monocytes and macrophages during acute infection than in CD4$^+$ cells.[10] HHV-6 also can infect multiple other cell types, including B lymphocytes, fibroblasts, natural killer cells, and neuronal, epithelial, and endothelial cells.[3,11,12] Growth is characterized by cellular ballooning, lysis, and cell death.

HHV-6A uses CD46 as a cellular receptor. This receptor is expressed on the surface of all human nucleated cells, which may partly explain the wide in vitro cellular tropism and tissue distribution of HHV-6A.[6] Viral binding occurs through the interaction of CD46 with the glycoprotein complex HHV-6A gHgLgQ1gQ2. The same complex is responsible for binding of HHV-6B to the newly identified receptor CD134 (OX40), a member of the tumor necrosis factor (TNF) superfamily present on the surface of activated T lymphocytes.[13] Differences in the nucleotide sequences gQ1 and gQ2 between HHV-6A and HHV-6B are thought to play a role in defining receptor specificity and tissue tropism.[9]

After primary infection HHV-6A and HHV-6B establish latency in monocytes and macrophages and possibly in other sites, such as hematopoietic stem cells ($CD34^+$) and the central nervous system (CNS).[14,15] Persistent infection can occur in the salivary glands.[15,16] The structure of the HHV-6 genome during latency appears to be maintained by chromosomal integration and/or by closed circular molecules, similar to episomes of other herpesviruses, and only a few viral genes are expressed.[3,17]

Reactivation occurs with multiple but poorly defined stimuli and can be asymptomatic or can result in organ-specific diseases.[18–20] Usually reactivation in a healthy person is clinically occult. Occasionally primary infection with a closely related virus (e.g., HHV-7) can result in HHV-6 reactivation associated with viremia and a febrile illness.[21]

Neutralizing antibodies to multiple HHV-6 proteins, especially to linear and conformational epitopes of the glycoproteins, develop after primary HHV-6B infection. Immunoglobulin M (IgM) antibody usually appears in the first week of illness and disappears within 1 to 2 months. IgG antibody appears during the second week after the onset of illness, and concentrations and avidity peak within 1 to 2 months.[3,15,22] The antibody response to primary infection occurs despite the presence of maternal antibody but can be dampened by high levels of passive antibody. Humoral antibody appears to be protective because illness is uncommon during the first few months of life when maternal antibody is present in high concentration (Fig. 207.1).[19] As transplacental antibody concentrations decline, infants rapidly acquire HHV-6B infection.[19] HHV-6 IgG antibody titers subsequently fluctuate and can be boosted by infection with other closely related herpesviruses. However, the immunologic response after primary infection usually protects against subsequent episodes of viremia and clinical illness. HHV-6 antibody is detectable throughout life, as evidenced by its almost universal presence in the cord blood of neonates.[23]

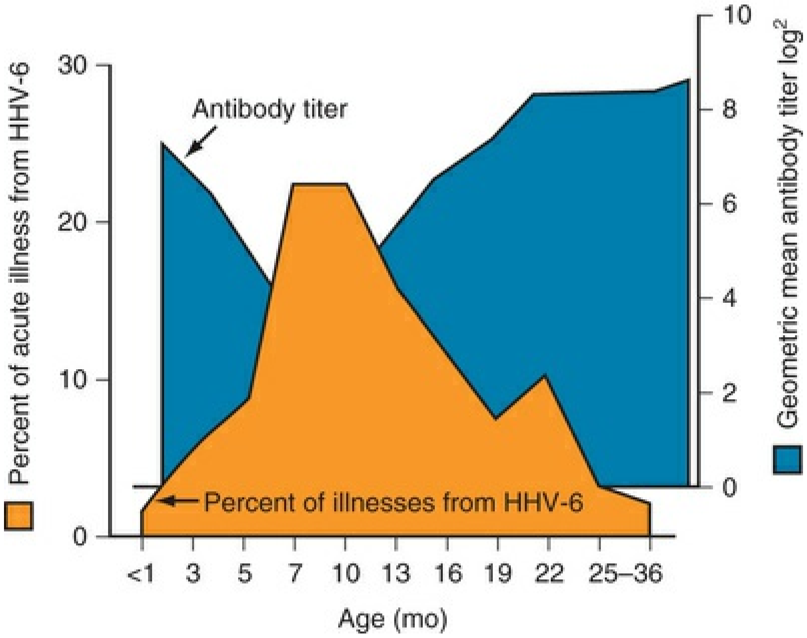

FIGURE 207.1 Percentage of visits to an emergency department in Rochester, NY, by children from birth to 36 months of age, attributable to acute febrile illness caused by primary infection with human herpesvirus 6 (HHV-6). The data are shown in relation to the average titer ($\log^2$) of antibody to HHV-6 present. (Data from Hall C, Long C, Schnabel K, et al. Human herpesvirus-6 infection in children: a prospective study of complications and reactivation. N Engl J Med 1994;331:432–438.)

Clinical observations suggest that cellular immunity is critical in the control, persistence, and reactivation of HHV-6B infection. Patients with compromised cellular immunity, especially hematopoietic stem cell (HCT) and solid-organ transplant (SOT) recipients, are most prone to developing disease with HHV-6B reactivation.[24–26] The effects of HHV-6 on the innate and adaptive cellular responses are incompletely defined but appear to be complex. Multiple observations indicate that HHV-6 can modulate and circumvent the body's immune response, enhancing the pathogenesis of primary infection and favoring lifetime survival of the virus.[3,27]

Epidemiology

HHV-6B infection has a worldwide distribution and no seasonal or gender predilection.[15,19,28] Primary infection usually occurs between 6 months and 3 years of age,[16,19] which matches the typical age distribution of roseola.[29,30] Studies of HHV-6B primary illness in Japan and the United States show similar age distributions, with relatively few cases before 6 months or after 2 to 3 years of age.[3,16,19] The peak period of acquisition is between 6 and 12 months; the median is about 8 months of age.[15,16,19,31]

HHV-6B is a major cause of acute febrile illness in infants 6 to 18 months of age, and it is responsible for about 20% of visits to emergency departments for acute illness in infants 6 to 12 months of age (see Fig. 207.1).[19,32] Infection is ubiquitous, and in most areas studied essentially all adults are seropositive.[15,19] Some geographic differences may exist, and in some countries the age of acquisition of initial infection is later than in the U.S.[33–35] HHV-6A has not been associated clearly with a distinct disease, and significant cross-reactivity between HHV-6A and HHV-6B in standard serologic assays has limited epidemiologic investigations.[36]

Mode of Transmission

Postnatal Infection

The major mode of transmission of HHV-6B to young children appears to be through respiratory secretions containing the virus that are asymptomatically shed by close contacts. This possibility is supported by data demonstrating that children who acquired HHV-6B infection before their first birthday were more likely to practice saliva sharing behaviors.[37] Additionally, HHV-6B DNA has been identified in 60% of nasal mucus specimens from healthy volunteers, which suggests that respiratory droplet transmission is probable.[38] In a prospective study of the epidemiology of roseola in 1941 Breese[29] observed that infants with roseola lacked a history of contact with children with similar disease and likely acquired the virus from asymptomatically shedding family members. Kempe and colleagues[30] in 1950 demonstrated that both the serum and respiratory secretions of an infant with clinical roseola could transmit the disease after an incubation period of 10 days in humans (after about 5 days in monkeys). Subsequent molecular and epidemiologic studies have confirmed that HHV-6B DNA is detectable after primary infection in peripheral blood mononuclear cells, saliva, and salivary glands.[15,16,39–41] Although HHV-6 persists in salivary glands, isolation of HHV-6B from oropharyngeal secretions is rare.[3,42,43]

Although the incubation period for HHV-6B infection has not been established, the Kempe study[30] suggests it is about 10 days, and primary infection has been documented in the first several weeks of life.[16,19,44,45] The detection of HHV-6B DNA in the genital secretions of pregnant women and in peripheral blood mononuclear cells of some infants in the first few weeks of life further supports the possibility of perinatal HHV-6B transmission.[19,44,46–49] Human milk is not a likely source of perinatal infection because the prevalence among breastfed and bottle-fed infants does not differ, and HHV-6 DNA has not been identified in human milk.[50,51]

HHV-6B is latent in bone marrow progenitor cells and therefore can be transmitted to recipients of bone marrow transplants or to those receiving solid-organ transplants.[52–55] HHV-6 infection with chromosomally integrated virus (ciHHV-6), characterized by high viral loads, also can be established in bone marrow recipients after transplantation from a donor with ciHHV-6.[56–59]

Congenital Infection

Congenitally acquired infections determined by detection of HHV-6 DNA in cord blood occur in about 1% of newborns.[23,60,61] Intrauterine HHV-6 infections can result from transplacentally passed maternal infection or from ciHHV-6 passed through the germline.[46,62] The latter appears to account for most (86%) congenital infections. HHV-6 has the unique ability among human herpesviruses to integrate as a whole, partial, or rearranged genome into chromosomes of some normal and immunocompromised individuals.[59,63–71] ciHHV-6 is estimated to occur in 0.2% to 1% of Japanese, United Kingdom, and U.S. populations.[62,69,71,72] Among the small number of people reported to have ciHHV-6 infection, integration has occurred invariably in the telomeric region of one chromosome's short or long arm.[17,62,71,73,74] Thus far at least eight different chromosomes have been identified.[63,69]

When ciHHV-6 is passed through the germline, the HHV-6 genome is present in every nucleated cell[57–59,62]; as a result, high viral loads are seen in all blood and other specimens.[57–59,62] These two distinctive biologic characteristics allow the diagnosis of ciHHV-6 infection by the detection of HHV-6 DNA in all cells of two different lineages (e.g., cord or peripheral blood mononuclear cells and hair follicles) or by demonstration of constantly and persistently high viral loads in peripheral blood mononuclear cells.[57–59,62] A sizeable proportion of these congenital infections are caused by HHV-6A, whereas HHV-6B accounts for essentially all postnatally acquired infections.[75] Children with ciHHV-6 infection have no distinctive clinical findings at birth.[62] However, one study found that children with ciHHV-6 had significantly lower global developmental test scores at 1 year of age compared with children without congenital HHV-6 infection, which supports a possible pathologic effect.[76] Evidence suggesting that ciHHV-6 can reactivate, replicate, and cause disease in immunocompromised people supports this as a possibility.[77–80]

Children with a transplacentally acquired congenital infection usually appear normal at birth. The initial diagnosis requires detection of HHV-6 DNA in cord blood mononuclear cells.[62,76] HHV-6 DNA subsequently can be detected in peripheral blood mononuclear cells and saliva, but not consistently or in the high viral loads observed with ciHHV-6 congenital infections. Most transplacentally acquired congenital infections appear to result from maternal reactivated ciHHV-6.[78,79]

Clinical Manifestations

Acute Febrile Illness

Yamanishi and associates[2] first isolated HHV-6B from four Japanese infants with roseola (exanthem subitum), the major clinical expression of primary HHV-6B infection in Japan.[81–83] In the U.S. a wide spectrum of febrile illnesses occur in infants with a primary infection (Fig. 207.2). Roseola is the clinical diagnosis in 10% to 30% of infected infants (Fig. 207.3).[16,19,31,84] Initial HHV-6B infection mimics a myriad of common, often nonspecific, illnesses of young children, making clinical differentiation difficult. However, some features provide clues to the diagnosis of HHV-6B infection, especially if the child is 6 to 24 months old. The abrupt onset of high fever (average, 40°C) is characteristic (see Fig. 207.2 and also Fig.

207.4). Children with an HHV-6B infection who were evaluated in emergency departments have shown substantially higher average temperatures and appear more acutely ill and irritable than age-matched children with acute febrile illnesses attributable to other etiologies.[19,31]

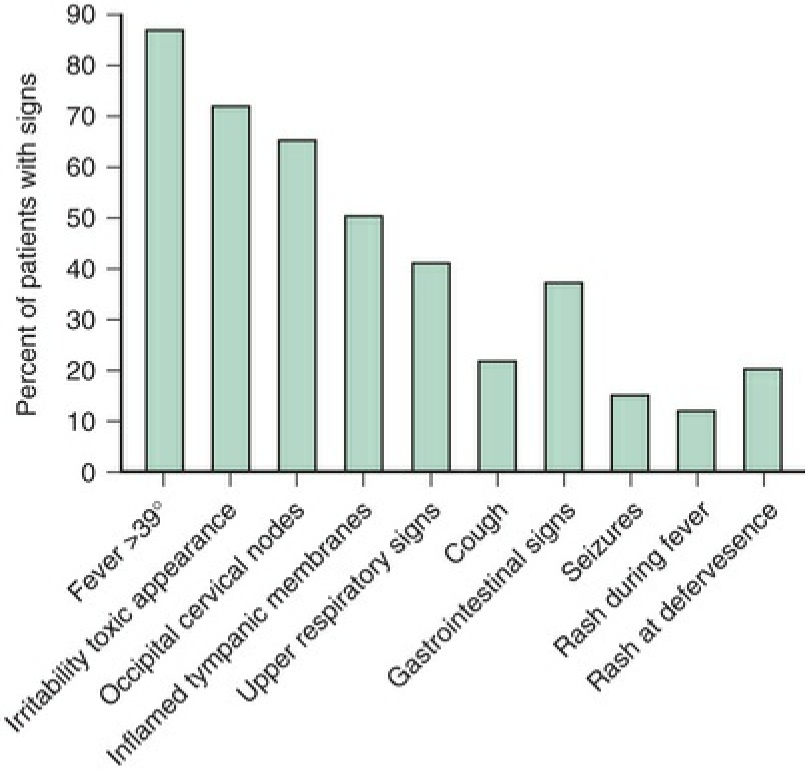

FIGURE 207.2 Clinical signs associated with a primary infection with human herpesvirus 6 (HHV-6) and the proportion of infected children who manifested each sign, as documented both by viremia and by seroconversion, in 335 children studied in Rochester, NY. (Data from Hall C, Long C, Schnabel K, et al. Human herpesvirus-6 infection in children: a prospective study of complications and reactivation. N Engl J Med 1994;331:432–438; and Hall CB. Human herpesvirus 6, 7, and 8. In: Gershon A, Katz S, Hotez P (eds). Krugman's Infectious Diseases in Children, 11th ed. Philadelphia, Mosby, 2003, pp. 277–291.)

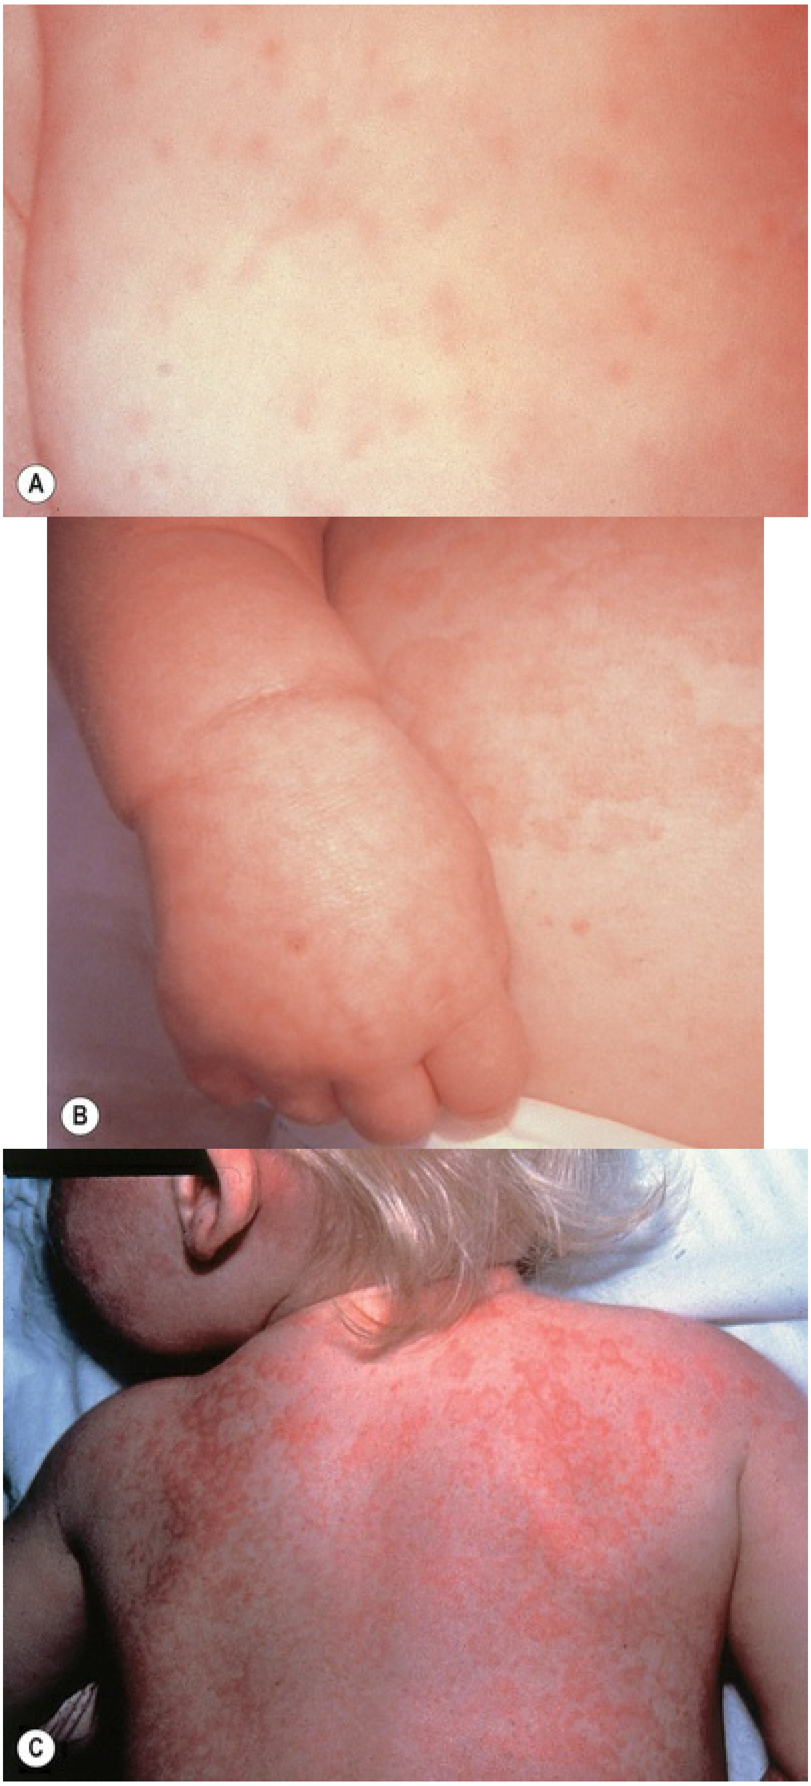

FIGURE 207.3 Exanthems associated with roseola. The rash observed with roseola historically was

described as the “rash of roses,” which denoted the sudden blooming of a pink to red exanthem. The lesions tend to appear first on the trunk, and then spread to the face and extremities. They can be morbilliform or can resemble rubella, with 1- to 3-mm macular, blanching lesions that sometimes coalesce into patches. As shown in A to C, the rash can vary in appearance and extent.

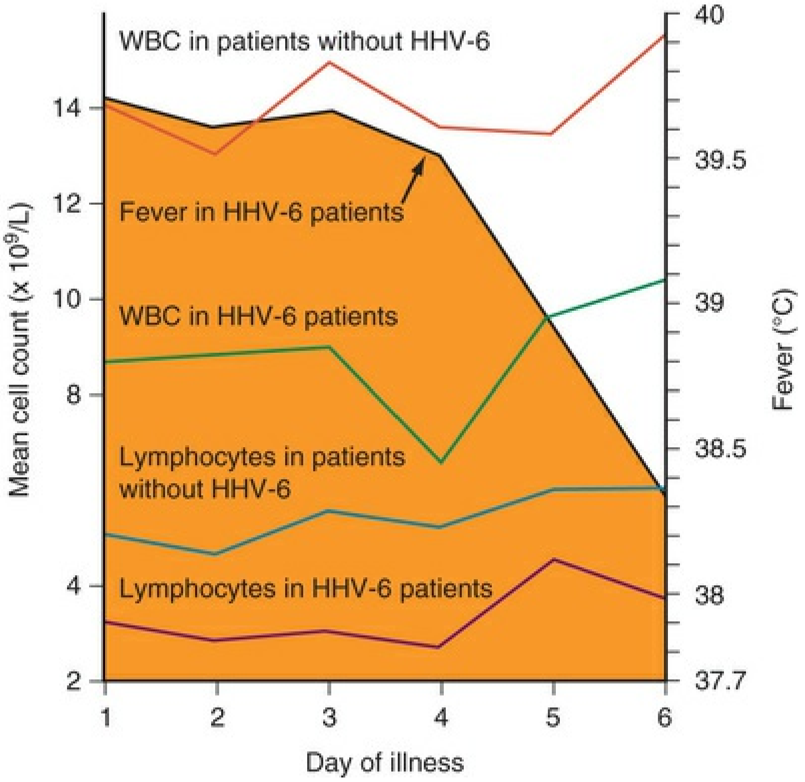

FIGURE 207.4 Mean total white blood cell (WBC) and lymphocyte counts in patients with a primary infection caused by human herpesvirus 6 (HHV-6). The counts are shown by day of illness in relation to the average course of the fever. For comparison, the figure shows the mean WBC and lymphocyte counts for children matched for age and season with similar acute febrile illnesses that were not caused by HHV-6. (From Pruksananonda P, Hall C, Insel R, et al. Primary human herpesvirus 6 infection in young children. N Engl J Med 1992;326:1445–1450.)

Among children ill with primary HHV-6B infection, about one third have fever with no localizing signs, one half manifest nasal congestion and other upper respiratory tract signs, and in about one third diarrhea and vomiting are prominent. Diffuse pharyngeal erythema, a mild maculopapular enanthem on the soft palate and uvula (Nagayama spots), and inflamed tympanic membranes are common. The eyelids can appear puffy and the palpebral conjunctivae erythematous. A maculopapular rash occasionally may be present during the early febrile phase rather than appearing later at defervescence, as is classic for roseola. Although mild cervical and postoccipital lymphadenopathy can be present at the initial evaluation, the distinctive prominent nodes in the posterior occipital region usually appear around days 3 to 4.[29,31]

The course of acute illness in most infants is 3 to 7 days. Fever usually remains high for 3 to 5 days (see Fig. 207.4). Recovery generally is rapid and complete after defervescence. Ten percent to 15% of infants with HHV-6B infection are hospitalized. The usual indications for admission include a toxic appearance and CNS manifestations, including seizures, a bulging fontanel, and encephalopathy.

Central Nervous System Manifestations

CNS manifestations are common among infants with a primary HHV-6B infection.[19,85] Case reports have noted the association between roseola and CNS signs, particularly a bulging anterior fontanel, which occurs in up to one fourth of patients with roseola.

Seizures are the most common manifestation of CNS involvement among infants with a primary infection.[19,31,86,87] HHV-6B infection has been identified as the cause of 10% to 20% of febrile seizures.[31,88] Among approximately 200 children younger than 24 months of age with a primary HHV-6B infection who were evaluated for acute illness in an emergency department, 13% had febrile seizures, which sometimes were recurrent or prolonged.[31] Only about one half of the seizures developed on the initial day of fever. In a prospective study of children with febrile status epilepticus, one quarter had a primary HHV-6B infection.[89] An association also appears to exist between the development of mesial temporal lobe epilepsy (MTLE) and HHV-6B infection of the hippocampus and amygdala that is persistent or reactivated years after the primary infection.[90,91] Although the detection rate for HHV-6B DNA does not appear to be uniformly higher in tissue samples from patients with MTLE, significantly elevated viral loads have been reported consistently.[90,91] These observations are in keeping with the recognized link between complicated febrile seizures and damage to the hippocampus, with subsequent mesial temporal sclerosis. HHV-6B infection of astrocytes that causes aberrant glutamate transport is one proposed mechanism linking viral infection with epilepsy.[92] Up-regulation of monocyte chemotactic protein-1 and glial fibrillary acidic protein RNA transcripts in amygdala specimens has been associated with HHV-6B viral loads in samples from patients with MTLE, suggesting that HHV-6B–induced neuroinflammation may play a role in pathogenesis.[91]

Reported cases of encephalitis and encephalopathy associated with HHV-6B primary infection have been variable in spectrum, severity, and outcome.[93–95] However, the incidence of HHV-6B encephalitis/encephalopathy and the full scope of clinical findings are unclear because mild cases in children likely are underreported. Although severe disease appears unusual in the U.S. and Europe, a national survey in Japan estimated that exanthem subitum–associated encephalitis/encephalopathy was responsible for 62 hospitalizations yearly, a rate of 5.5 per 100,000 cases of exanthem subitum.[96] Neurologic sequelae were reported in 47% of cases, and 2.5% of these patients died. Acute encephalopathy with biphasic seizures and late reduced diffusion (AESD), a newly defined subtype of encephalopathy in Japan, is reported most commonly in association with primary HHV-6B infection.[85,97,98] The fatality rate for AESD is low, but full recovery is noted in less than one third of patients.[97,98] Severe CNS syndromes in patients with primary HHV-6B infection and thermolabile variants of carnitine palmitoyltransferase 2, an enzyme involved in energy metabolism, have been reported in Japan.[85,99,100] Two infants with *POLG* mitochondrial mutations and severe encephalitis with progressive encephalopathy associated with primary HHV-6B infection have been reported in the U.S.[101] Taken together these observations suggest that primary HHV-6B infection may act as a trigger for severe neurologic disease in genetically susceptible individuals. Confirmation of this possibility in a larger number of cases might help explain population differences in the incidence of severe encephalitis/encephalopathy associated with primary infection.

Clinical and laboratory findings associated with CNS disease complicating primary HHV-6B infection generally are not distinct from those seen in other infectious causes of encephalitis/encephalopathy. Cerebrospinal fluid (CSF) abnormalities are infrequent.[85,96] Magnetic resonance imaging can produce normal findings, or it can show transient involvement of cerebral white matter or involvement of multiple areas of the brain, including the temporal lobe, hippocampus, and amygdala.[102–104]

Encephalitis caused by reactivation of HHV-6B in immunocompetent adults and children is rare, and case reports likely are confounded by ciHHV-6.[105] However, the syndrome of posttransplant acute limbic encephalitis (PALE) caused by HHV-6B reactivation has been described, especially in those undergoing HCT.[106] Clinical risk factors associated with the development of PALE include receipt of an umbilical cord blood transplant (UCBT) or a mismatched adult donor transplant, and the development of acute graft-versus-host disease (GvHD). The incidence ranges from 0.5% to 8.3% and is significantly higher among patients receiving a UCBT.[106–108] Reactivation of HHV-6B, with high levels of viral DNA identified in plasma, has been associated with the onset of PALE, suggesting that a substantial viremia immediately precedes or is coincident with the development of disease.[106,109] Commonly reported symptoms include altered mental status with confusion, insomnia, hallucinations, anterograde amnesia, seizures, and the syndrome of inappropriate secretion of antidiuretic hormone. Symptoms typically occur 2 to 6 weeks after transplantation.[107,109–111] Imaging abnormalities are identified frequently in the medial temporal lobes, specifically in the hippocampus, amygdaloid complex, and entorhinoral cortex, which consist of T2 hyperintense lesions on fluid attenuation inversion recover (FLAIR) images.[107,109–111] Long-term neurologic sequelae, including generalized epilepsy and cognitive decline, frequently have been reported in children.[85,112,113] In addition to PALE, an association between HHV-6B reactivation and the development of delirium and neurocognitive decline was identified in a prospective study of patients after HCT, suggesting that HHV-6B reactivation causes more varied and widespread CNS dysfunction in this patient population than previously recognized.[114]

The diagnosis of HHV-6 as a cause of CNS disease in both normal and immunocompromised patients often is made by detection of

HHV-6B DNA in the CSF and sometimes in CNS tissue. However, the diagnosis may be confounded by the presence of ciHHV-6 or the ability of HHV-6 to become latent in the CNS of healthy and diseased individuals.[105,115–117] HHV-6B DNA is commonly detected in the CSF of children during primary HHV-6 infection and also can be identified after acute infection.[117–120] Additionally HHV-6B viral DNA can be detected in the CSF without neurologic signs or symptoms in patients after HCT, which suggests that asymptomatic reactivation in the CNS can occur.[121] The currently accepted criteria for the diagnosis of PALE are detection of HHV-6B DNA in the CSF of a transplant recipient with persistent neurologic symptoms and no alternative explanation.[106,122]

Other Associated Illnesses

Many uncommon findings have been associated with primary HHV-6 infection, but a causal role of HHV-6 remains unclear. Among these uncommon findings are a severe febrile course with recurrent rash and arthritis, hepatitis, hemophagocytic syndrome, thrombocytopenia, granulocytopenia, cardiomyopathy, drug-induced hypersensitivity syndrome, an infectious mononucleosis-like syndrome, and Gianotti-Crosti syndrome.[22,123–126]

Diagnosis

No clinical or laboratory finding at the time of initial assessment is sufficiently specific or distinctive to assure accurate diagnosis of an HHV-6B primary infection (see Fig. 207.4). Multiple assays are available to detect the infectious virus, HHV-6B antigens, nucleic acids, and antibodies (Table 207.1). Nevertheless, the diagnosis is confounded by the ubiquity of infection, subsequent latency, and ciHHV-6, making differentiation of acute HHV-6B infection from past latent infection or ciHHV-6 difficult.[127] Primary infection is best ascertained by the isolation of HHV-6B from peripheral blood mononuclear cells (testing limited to research laboratories) and seroconversion, or by serologic confirmation of new infection. Diagnosis based solely on a rise in antibody titers, seroconversion, or even virus isolation can be misleading (Table 207.1). Viremia is rare in healthy children except during a primary infection. However, viremia can occur during reactivation in immunocompromised patients and occasionally in immunocompetent children experiencing primary infection with other β-herpesviruses.[128] Marked fluctuations in antibody titer may result from changes in the replicative state of latent virus and from cross-reactive antibodies. Absence of detectable seroconversion in infants can result from the presence of passive maternal antibody. However, some currently available assays for virus antigen and HHV-6B DNA and RNA allow differentiation of active, productive infection from latent infection, and ciHHV-6 (Table 207.1).[127,129]

TABLE 207.1

Diagnosis of Infections Caused by Human Herpesvirus 6 (HHV-6) and Human Herpesvirus 7 (HHV-7)

		Type of Infection Diagnosed				
Assay[a]	**Specimen**	**Acute Primary**	**Recent Active**	**Past/Latent**	**Reactivated**	**Comments**
SEROLOGY[b]						
Antibody Titers	Serum/plasma					
IgG titers		+	+	+	±	Sensitive. Seroconversion indicates primary infection HHV-6 species are not differentiated HHV-6 and HHV-7 cross-reactivity is limited, depending on assay used Results are not available during acute illness because testing of two or more serial specimens is required Single specimen that is antibody negative and DNA positive suggests early, primary infection Maternal antibody can be present in infants <6 mo of age; confounds results
IgM titers		+	+			Not detected in all primary infections

						May be detected in a small percentage of healthy people and in some reactivated infections
Avidity titers		+	+	+		Testing of single specimen indicates acute infection within 6 wk (low avidity) or after 6 wk (high avidity)
DNA/RNA DETECTION						
DNA PCR	Mononuclear cells in blood and other specimens	+	+	+	+	DNA detection can indicate acute and/or past infection; requires serology and/or RT-PCR for clarification Differentiates HHV-6 species
	Serum/plasma or whole blood	+			+	Lysis of peripheral blood mononuclear cells can produce appreciable proportion of false-positive results[127,218]
Real-time DNA PCR	Serum/plasma or whole blood	+			+	Quantitative, very sensitive, costly Lysis of peripheral blood mononuclear cells can produce an appreciable proportion of false-positive results[127,218]
RNA PCR						
RT-PCR	Mononuclear cells	+			+	Very sensitive, semiquantitative Differentiates HHV-6 species, costly
Real-time RT-PCR	Mononuclear cells	+			+	Very sensitive, quantitative, costly
VIRAL GROWTH AND DETECTION						
Viral growth	Mononuclear cells of blood and other specimens	+			+	Available only in research laboratories HHV-6 species can be differentiated Results usually are not available during acute illness
Viral antigen detection	Blood, secretions	+			+	Suggests active replication, semiquantitative Differentiates HHV-

						6 species Sensitivity and specificity variable

[a] Congenital infection with HHV-6 can confound interpretation of diagnostic tests; see text on Congenital Infections.

[b] Multiple serologic tests are available including immunofluorescent assays (IFA), neutralizing antibody assays, enzyme immunoassays (EIA), immunoblots, anticomplement assays.[2,3,15,214,215]

Ig, immunoglobulin; DNA, deoxyribonucleic acid; RNA, ribonucleic acid; PCR, polymerase chain reaction; RT-PCR, reverse transcriptase PCR; HHV-6, human herpesvirus 6.

Management and Therapy

Because primary HHV-6 infection generally is benign and self-limited, management consists mainly of supportive treatment, control of fever, and adequate fluid intake.

Antiviral therapy has been used primarily in immunocompromised patients and those who have severe disease (e.g., PALE). However, no antiviral agent has been approved for the treatment or prevention of HHV-6 infections. Currently available antiviral agents that have been used for HHV-6B infections are ganciclovir, foscarnet, valganciclovir, and cidofovir.[3,122,130] These agents inhibit replication in vitro. Ganciclovir or foscarnet (or a combination of the two drugs) is used most commonly. The results for benefit of treatment have been mixed, but no controlled trials exist. Resistant HHV-6B strains have been reported.[3,131,132] Many new antiviral compounds are in development. Some that appear promising include both nucleoside/nucleotide analogues and nonnucleoside analogues, including brincidofovir (CMX001), and the antimalarial drug artesunate.[3,130] Additionally, generation of HHV-6B–specific T-cell clones for use in immunotherapy has been described.[133]

Complications in Special Patient Populations

The role of HHV-6 in the genesis of cancer is unclear, and the question is complicated by viral latency in diverse body sites.[20] Reactivation of HHV-6B occurs in approximately 20% to 50% of immunocompromised patients. The highest rates are observed in bone marrow and solid-organ transplant recipients.[3,26,108,109,134] HHV-

6B reactivation usually occurs in the first 2 to 4 weeks after transplantation and can be accompanied by viremia. Whether disease is associated with the reactivation of endogenous HHV-6B infection or reactivation associated with transplantation is not clear and is confounded by the presence of other opportunistic infections.[135,136] Most HHV-6B reactivations are asymptomatic, but a variety of associated findings and symptoms have been reported. Most frequent are fever and rash, sometimes with leukopenia. Acute GvHD, myelosuppression, interstitial pneumonitis, hepatitis, graft failure, and delayed engraftment (especially of platelets), in addition to CNS disease and death, have been associated with HHV-6B reactivation.[26,52,122] The risk of HHV-6B reactivation has been correlated with the degree of immunosuppression, unrelated solid-organ and cord blood donor, low anti-HHV-6 antibody titers before transplantation, young age, and the concurrence of other herpesvirus infections.[20]

HHV-6 has been shown in vitro to act as a cofactor in augmenting HIV infection and simian immunodeficiency disease (SIV) in a macaque animal model.[137-139] However, the adverse consequences of HHV-6B infection in patients with HIV or AIDS are less clear, and progression of HIV disease caused by HHV-6 reactivation has not been proven.[20,140]

Interest in the contribution of HHV to the development of demyelinating disease, primarily multiple sclerosis (MS), has been sparked by the identification of HHV-6 DNA in the oligodendrocytes of MS plaques and the greater frequency of detection of HHV-6 DNA and proteins in specimens from patients with MS compared with unaffected controls.[141,142] Additional studies have found active HHV-6 replication in blood, CSF, and CNS specimens in patients with relapsing and remitting MS.[143-145] Recent evidence includes the identification of oligoclonal bands specific for HHV-6A and HHV-6B from the CSF of patients with demyelinating disorders.[146] However, findings associating HHV-6 with MS are inconsistent and require further clarification.[147]

Human Herpesvirus 7

The discovery of *Human herpesvirus 7* in the peripheral blood lymphocytes of a healthy adult was reported 4 years after the initial isolation of HHV-6.[148] As mentioned earlier, HHV-7, HHV-6A, and HHV-6B are closely related biologically.[22,149] Similar to HHV-6B, primary infection with HHV-7 occurs in most individuals during childhood, and persistent infection is established in the salivary glands. In contrast to HHV-6B, HHV-7 can be isolated easily from the saliva of previously infected individuals.[42,149] Furthermore, clinical expression of HHV-7 infection appears to be substantially less common, and its virologic characteristics and cellular tropism differ from those of HHV-6A and HHV-6B.

Description of the Pathogen

HHV-7 belongs to the *Roseolovirus* genus of the β-Herpesvirinae subfamily. Among the human herpesviruses, HHV-7 is most closely related to HHV-6A, HHV-6B, and CMV.[149] The genomic structure and properties of HHV-7, HHV-6A, and HHV-6B are similar. They have genetically colinear genomes with analogous gene arrangements. However, the HHV-7 genome is more compact, and it is about 10% shorter in length. The amino acid sequence identity between HHV-6 and HHV-7 ranges from 24% to 83%. The antigenic relatedness between the viruses is sufficient to result in serologic cross-reactivity. Little variation among strains exists (about 0.1%), and no HHV-7 variant groups have been identified. The HHV-7 genome encodes approximately 86 different proteins, some of which appear to be unique to the β-herpesviruses.[149]

The growth properties of HHV-7 and its cytopathic effects in cell culture resemble those of HHV-6.[42] HHV-7 is tropic for $CD4^+$ T lymphocytes and, in contrast to HHV-6A and HHV-6B, it uses the $CD4^+$ molecule for at least part of its essential receptor for cell entry.[150] Isolation of HHV-7 requires growth in primary phytohemagglutinin-stimulated $CD4^+$ T lymphocytes from peripheral blood mononuclear cells or cord blood, or in a continuous $CD4^+$ lymphoblastic cell line, SupTl. The cytopathic effect, characteristic of both HHV-6 and HHV-7, is ballooning, refractile, multinucleated giant cell formation.[42,149] HHV-7 usually grows more slowly and is less cytopathic than HHV-6.

HHV-7 establishes both active and latent infection in $CD4^+$ T lymphocytes and readily produces ongoing persistent infection in the salivary glands.[42,149] HHV-7 latent or persistent infection has been detected in a wide range of tissues, including skin, lungs, mammary glands, tonsils, liver, and kidneys. In vitro, HHV-7 infects but does not replicate in monocytes and macrophages. HHV-7 also infects CD34$^+$ hematopoietic progenitor cells and CD68$^+$ monocytes and macrophages in lesions of Kaposi sarcoma.[151–153]

Epidemiology

The epidemiology of HHV-7 has been determined mostly from seroepidemiologic studies.[15,42,154,155] Infection is ubiquitous in childhood, acquired more slowly and later than HHV-6B infection.[128,156] The median age of acquisition is about 2 years. In Rochester, New York, about 20% of healthy children acquired HHV-7 by 1 year, 50% by 2 years, and 75% by 5 years of age.[128,156] The prevalence of HHV-7 antibody gradually rises thereafter, reaching 80% to 98% in adults, and passive antibody is present in almost all newborns.[128,157] HHV-7 and HHV-6B infections appear to be acquired independently, but cross-reacting antibodies from the initial infection of one may exert some protective effect against the acquisition or clinical expression of the other.[15,42,128,158]

Transmission of HHV-7 likely occurs most frequently from contact with the saliva of previously infected people. Infectious virus is shed in the saliva of more than 90% of adults.[15,42] The detection of HHV-7 DNA in 3 of 29 human milk samples suggests another possible means of transmission to infants.[159] However, antibody to HHV-7 also has been detected in human milk, and breastfeeding has been associated with a lower risk of early acquisition of HHV-7 infection.[156,159] Although HHV-7 infection during the first months of life is uncommon, perinatal transmission can result from contact with infected maternal cervical secretions at birth.[46,128,160,161] HHV-7 DNA has been detected in the cervical swabs of 2.7% to 9.6% of pregnant women, and in 0% to 3% of nonpregnant control women.[46,49,161] Despite this, and in contrast to HHV-6A and HHV-6B, intrauterine transmission of HHV-7 does not appear to occur.[23,46]

Clinical Manifestations

The clinical presentation of primary HHV-7 infection resembles that of HHV-6B.[128,158,162–166] Acute HHV-7 infection has been identified in a few children with febrile illnesses, which may explain the occasional observation of second or recurrent cases of roseola. However, clinical disease with a confirmed primary infection has been reported infrequently, which suggests that most primary HHV-7 infections are asymptomatic or mild.

Among the few reported cases of primary HHV-7 infection, the most common presentation is a nonspecific, highly febrile illness.[128,158,162–166] However, CNS manifestations, especially febrile seizures and status epilepticus, occur in a high proportion of infections.[87,89] Of 8 children with primary HHV-7 infection demonstrated by isolation of the virus from the blood and seroconversion, 6 had seizures accompanying the febrile illness (Table 207.2).[158] HHV-7 also has been associated with more serious neurologic manifestations, including encephalitis, Guillain-Barré syndrome, and hemiplegia, especially with delayed primary infection.[22,117,167–169] HHV-7 DNA has been detected in the CSF of a few patients with and without neurologic disease and in about 5% of brain tissue samples from healthy adults.[a]

TABLE 207.2

Clinical and Laboratory Findings in Patients With Primary Infections Caused by Human Herpesvirus 7 (HHV-6) and Human Herpesvirus (HHV-6)

	HHV-7	HHV-6	P
Median age (months)	26	9	0.001
Range	3–34	1–28	
Mean temperature (°C)	39.8	39.8	NS
Range (°C)	38.9–40.4	37.8–40.6	
Seizures (%)	6 (75)	5 (17)	0.004
Irritability (%)	7 (88)	20 (69)	NS
Vomiting or diarrhea (%)	3 (38)	10 (34)	NS
Rash (%)	1 (13)	14 (48)	0.11
Hospitalized (%)	1 (13)	5 (17)	NS
Mean days of fever	3	4	NS
Mean WBC count (× 10^3/mm^3)	7.44	6.31	NS
Range (× 10^3/mm^3)	4.2–13.3	3.6–13.9	
Mean absolute lymphocyte count (× 10^3/mm^3)	1.85	2.63	NS
Mean absolute neutrophil count (× 10^3/mm^3)	4.93	2.86	0.018

From Caserta T, Hall CB, Schnabel KC, et al. Primary human herpesvirus 7 infection: a comparison of human herpesvirus 7 and human herpesvirus 6 infections in children. J Pediatr 1998;133:386–389.

Much interest has arisen in the potential immunomodulatory effects of HHV-7 infection. As with HHV-6, HHV-7 encodes genes that can alter, inhibit, and evade the immune response elicited by HHV-7 infection. An important mechanism of host evasion is the downregulation of both class I major histocompatibility (MHC) molecules and natural killer (NK) cell–activating ligands by the HHV-7 U21 gene product.[174,175] In addition HHV-7 can downregulate the expression of $CD4^+$ on T lymphocytes, and it encodes two functional β-chemokine receptors by means of the open reading frames U12 and U51, similar to the previously identified CMV and HHV-6 homologues.[150,174,176–180]

The downregulation of $CD4^+$ expression potentially can exert a beneficial effect. Both HHV-7 and HIV-1 use the $CD4^+$ molecule as a receptor for T-lymphocyte infection, and HHV-7 infection has been shown to produce an antagonistic effect on HIV infection of $CD4^+$ T lymphocytes. This appears not to be dependent on viral replication, but more likely represents competition for the $CD4^+$ receptor.[181–184] HHV-7 DNA has been found more frequently among HIV-seropositive patients than those who are HIV-seronegative, and among HIV patients who have long-term, nonprogression compared with those with progressive disease.[181] However, no relationship between viral loads of HHV-7 and HIV or $CD4^+$ T lymphocytes has been observed. Clinical correlates require further study.[181]

The role of HHV-7 in causing disease among immunosuppressed patients is less clear than that of HHV-6B, although often the two are reactivated simultaneously.[122,185,186] In these patients, HHV-7 infection is most likely reactivation of a latent endogenous infection, considering the high prevalence of HHV-7 infection at an early age. However, primary infection can occur (especially among seronegative young children), acquired from the secretions of close contacts or from donor-positive transplants. Information is limited on the frequency of occurrence of active HHV-7 infection in immunodeficient groups of people. Active HHV-7 infection affects up to 88% of solid-organ transplant recipients; in addition, like HHV-6B, it occurs about 2 to 4 weeks after transplantation.[185–187]

HHV-7 appears to be less pathogenic than HHV-6B, causing disease in less than 1% of solid-organ transplant recipients.[186] However, pathogenicity is difficult to assess because infection is ubiquitous and multiple other infections occur simultaneously in immunocompromised patients.[187,188]

Although symptomatic disease caused by HHV-7 has not been demonstrated clearly in transplant recipients, fever and CNS disease have been reported with reactivated HHV-7 infection.[186,189] Diminished survival time and acute GvHD also have been associated with HHV-7 infection. Unlike with HHV-6B infection, however, the circulating load of HHV-7 does not correlate with disease.[185,187,190] Reactivated HHV-7 infection also has been suggested as a cofactor in CMV reactivation and progression to disease in solid-organ transplant recipients, but the evidence is conflicting.[186,187,191–194]

Multiple studies have explored the association between HHV-7 infection and various skin diseases; however, whether the virus plays a role is unclear, and the question is confounded by the detection of HHV-7 in normal skin.[195–199] HHV-7 has been detected more frequently in biopsy specimens from patients with pityriasis rosea than from controls, and it has been isolated from the peripheral blood mononuclear cells of patients with pityriasis rosea during acute illness. Other studies, however, have not verified a role for HHV-7 in pityriasis rosea.[200–202]

HHV-7 has been associated anecdotally with a variety of other syndromes, including connective tissue and autoimmune diseases, chronic fatigue syndrome, hepatitis, a mononucleosis-like syndrome, and Kawasaki disease, but these associations remain unproven.[42,203–212]

Diagnosis

Many diagnostic tests can detect the presence of HHV-7 infection, but they do not determine the correlation with acute clinical manifestations because tests do not differentiate primary, past, latent, and reactivated HHV-7 infection (see Table 207.1). Active infection can be identified by the detection of HHV-7 RNA or suggested by the detection of HHV-7 at multiple times in some specimens (e.g., plasma), or these tests can be combined with the determination of viral loads or serologic studies (see Table 207.1).[15,127,129,213–215]

Management and Therapy

Specific antiviral therapy for HHV-7 generally is not needed because most primary and reactivated HHV-7 infections are asymptomatic or mild, both in normal and immunocompromised children.[122,186] Compounds similar to those that inhibit HHV-6 have variably suppressed the growth of HHV-7 in vitro. However, the clinical benefit of antiviral agents for HHV-7 infection has not been determined adequately, and no controlled trials exist.[216] Limited evidence suggests that ganciclovir has no impact on the reactivation of HHV-7 in solid-organ recipients.[186,217] Antiviral drugs, therefore, usually are not recommended for use therapeutically or prophylactically. More effective measures may be to reduce the immunosuppression that augments both the reactivation of HHV-7 and, more important, the manifestations associated with other commonly concurrent opportunistic viruses, such as CMV.

The author acknowledges the substantial contribution of Caroline Breese Hall in previous editions of this chapter. The infectious diseases community recognizes her major contributions to our field and feels great sadness about her loss. – Sarah S. Long

Key Points

Epidemiology, Clinical Features, Diagnosis and Management of Roseolovirus Infections

Epidemiology

- Human herpesviruses 6 (HHV-6A, HHV-6B) and HHV-7 comprise the *Roseolovirus* genus of the β-herpesviruses subfamily (β-Herpesvirinae).
- Primary infection with HHV-6B occurs almost universally by 3 years of age, with peak acquisition at 6 to 12 months of age.
- After primary infection HHV-6B remains latent or persistent at several body sites, including the central nervous system and salivary glands.

- HHV-6 integrates into the host genome in about 1% of the U.S. population and is passed by means of germline transmission.
- The major mode of transmission of HHV-6B is through respiratory secretions from asymptomatic close contacts, which occurs year round.
- Ten percent to 15% of children with primary HHV-6B infection are hospitalized.
- Primary HHV-6B infection accounts for approximately 20% of emergency department visits for acute illness in infants 6 to 12 months of age.
- HHV-7 causes ubiquitous infection in childhood; 75% of children are infected by 5 years of age.

Clinical Features

- HHV-6B infections

- High fever, fussiness, and nasal congestion are the most common symptoms in infants with a primary infection.
- Fever usually begins abruptly and typically lasts 3 to 7 days.
- Only 25% of primary infections in the United States manifest as roseola infantum.
- Seizures, including febrile status epilepticus, are the most common complications.
- Posttransplant acute limbic encephalitis (PALE), caused by reactivation of HHV-6B, is a serious complication in immunocompromised patients,

especially after transplantation of umbilical cord blood.

- HHV-7 infections
  - Most infections are mild and transient, although complications (e.g., seizures) can occur with primary infection.
- HHV-6A infections
  - Primary infection has been described rarely and is not associated with any known illness or disease.

Diagnosis

- Primary HHV-6B infection can be confirmed using the combination of seroconversion and detection of viral DNA in plasma.
- Diagnosis of PALE requires detection of HHV-6B DNA in the cerebrospinal fluid of a transplant patient with persistent neurologic symptoms that have no alternative explanation.

Management

- Most primary infections with roseoloviruses are self-limited and do not require specific treatment.
- No antiviral medications are currently licensed for the treatment of roseolovirus infections.

Epstein-Barr Virus (Mononucleosis and Lymphoproliferative Disorders)

Ben Z. Katz

Epstein-Barr virus (EBV), a ubiquitous herpesvirus of humans, was discovered in 1964. The causal relationship between EBV and infectious mononucleosis (IM) was observed in 1968.[1] The spectrum of associated infections ranges from asymptomatic, to self-limited mononucleosis in healthy hosts, to progressive infections in patients with acquired or inherited disorders of immunity.[2]

Description of Pathogen

EBV is a γ-herpesvirus. Mature, infectious particles are 150 to 200 nm in diameter and are composed of a 172-kb, double-stranded DNA genome, capsid, protein tegument, and lipid-containing outer envelope. The viral capsid has icosahedral symmetry and is composed of 162 capsomeres.[3] The entire nucleotide sequence of several strains is known.[4] EBV, like other herpesviruses, is easily degraded and has a latent and a lytic life cycle.

Latent and Lytic Life Cycles.

Cells that are latently infected with EBV grow continuously, the viral genome is maintained as a circle (plasmid), a limited number of regions of the EBV genome are transcribed, and a relatively small number of viral proteins are synthesized. One latent protein, Epstein-Barr nuclear antigen-1 (EBNA-1), is necessary for plasmid maintenance. Cells that are permissive to the lytic life cycle (differentiated plasma cells and differentiated epithelial cells) linearize the EBV genome, transcribe a larger portion of the genome than latently infected cells, synthesize more proteins, release infectious EBV, and perish. The switch between latency and replication is tightly regulated and is initiated by two EBV early proteins termed BZLF1 or ZEBRA and BRLF1.[3] Another EBV protein, BCRF1, is homologous to IL-10 and stimulates B-cell proliferation while suppressing T-cell proliferation.[2]

In vitro, the virus has a narrow host range and infects B lymphocytes of humans and other primates. In vivo, the virus also can be found in epithelial cells, T lymphocytes, or natural killer (NK) cells.[5–7]

B-Lymphocyte Immortalization and Activation.

Generally, EBV infects B lymphocytes and confers on them the ability to grow continuously in cell culture, a process termed *immortalization*. B-lymphocyte immortalization is the hallmark of EBV infection. EBV latent membrane protein (LMP)-1 mimics B-lymphocyte activation antigen CD40,[8] promoting B-lymphocyte activation and immortalization by preventing programmed cell death (apoptosis). LMP-2 prevents EBV from reactivating in latently infected B cells. The role played by EBV latent proteins in the immortalization process has been reviewed.[9]

EBV Antigens.

Up to 11 messenger RNAs (mRNAs) and 9 EBV antigens are expressed during latency. EBNA, the classic EBV-induced latent neoantigen defined by immunofluorescence microscopy, is composed of 6 proteins (including EBNA-1). About 60 mRNAs are produced when the virus replicates lytically. Early antigens (EAs) are lytic proteins produced by the virus before viral DNA replication; these antigens consist mainly of viral enzymes necessary for genome replication. The classic EA complex, also defined by immunofluorescence microscopy, consists of diffuse (EA-D) and restricted (EA-R) components. The viral capsid antigen (VCA) is the classic EBV late antigen and is synthesized after EBV DNA replication. Genes encoding some of these classic EBV lytic antigens have been identified.[3]

Epidemiology

In developing countries and in lower socioeconomic populations in industrialized nations, up to 90% of children contract EBV infection by 8 years of age. In contrast, in higher socioeconomic groups, from 30% to 75% of adolescents are EBV seronegative[10] (Fig. 208.1).

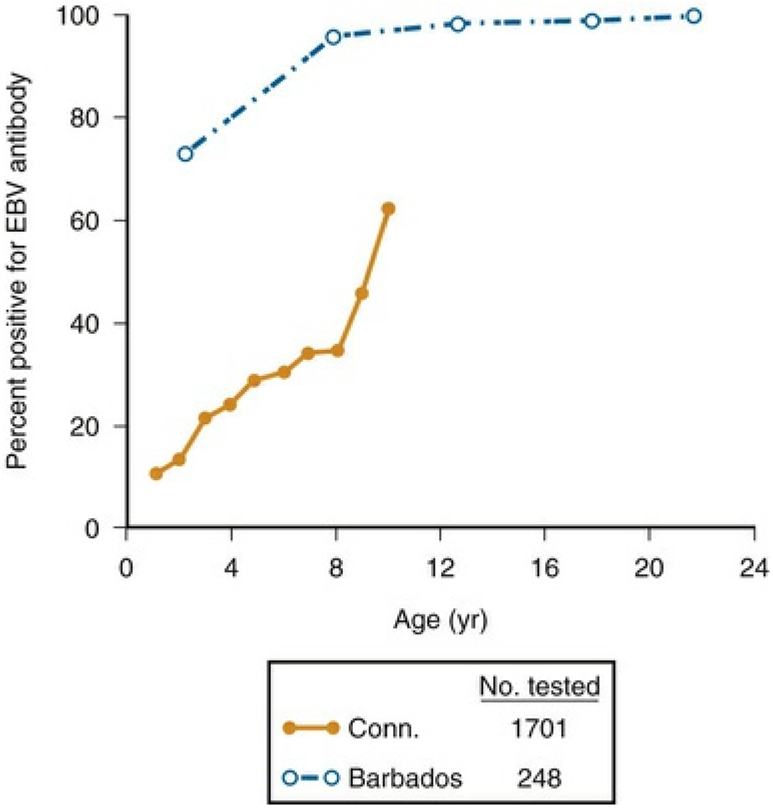

FIGURE 208.1 Differences in rates of acquisition of Epstein-Barr virus (EBV) by socioeconomic status. In Connecticut, by 8 years of age, only 30% of children are EBV seropositive, whereas in Barbados, by the age of 8 years, 90% have been infected with the virus. (Modified from Evans AS, Niederman JC. Epstein-Barr virus. In: Evans AS (ed). Viral Infections of Humans: Epidemiology and Control, 3rd ed. New York, Plenum, 1991, p. 265.)

Young children who acquire primary EBV infection usually do so asymptomatically or with only mild, nonspecific symptoms. IM occurs mainly in adolescents and young adults of higher socioeconomic groups who escaped primary EBV infection when younger. Approximately 1% to 5% of susceptible adolescents and adults contract EBV infection annually, about one half of whom develop symptomatic IM.[11] Many of the symptoms of IM are secondary to the immune response directed at EBV. The annual incidence of IM in the United States is about 500 per 100,000; peak ages affected are 15 to 24 years.[10]

EBV is shed in oropharyngeal secretions during acute infection and intermittently thereafter; these secretions are the major source of infectious virus. It is not clear how EBV transitions between B lymphocytes and oral epithelium; however, because patients with X-linked agammaglobulinemia do not contract EBV infection, B lymphocytes must play a critical role in this process.[8,12]

Infection usually is transmitted through close personal contact. EBV also can be transmitted sexually.[11,13,14] Infection is only modestly communicable, and secondary attack rates are low. Rarely, transmission of IM has been documented after blood transfusion.

Pathogenesis of Infectious Mononucleosis in Previously Healthy Children

Infection in a susceptible person probably begins in the epithelial cells of the buccal mucosa or salivary glands. Subsequently, virus gains access to B lymphocytes (probably memory B lymphocytes,[15] the primary site of EBV persistence) in the lymphoid tissue of the pharynx, and disseminates to the entire lymphoid system (Fig. 208.2). CD21, the major B-lymphocyte receptor for EBV, binds to the viral glycoprotein gp350. Various HLA molecules can act as coreceptors, and other viral glycoproteins allow the virus to penetrate the cell.[16,17]

Early in the course of primary EBV infection, up to 20% of circulating B lymphocytes are infected and immortalized, with EBV DNA present within their nuclei. Most of the characteristic atypical lymphocytes of IM are activated, EBV-specific cytotoxic/suppressor T lymphocytes, which account for up to 30% of the $CD8^+$ T cells in the blood of patients with IM. These cells can kill EBV-infected B lymphocytes and are themselves subject to enhanced apoptosis.[18,19] NK lymphocytes that lyse EBV-infected B lymphocytes also are produced.[20] Probably because of this $CD8^+$ T-lymphocyte and NK-cell activity, a transient general depression in cellular immunity can occur during acute IM, with anergy to skin test antigens and decreased lymphocyte responses to plant mitogens, soluble antigens, and mixed leukocyte culture.[1,18–20] Infection ultimately is brought under control by a combination of neutralizing antibodies, cytotoxic T lymphocytes, NK cells, and their secreted products (e.g., lymphokines).

Clinical Aspects of Infectious Mononucleosis

Clinical Manifestations

EBV causes almost all cases of heterophil-positive and most cases of heterophil-negative IM. Other causes of heterophil-negative mononucleosis include cytomegalovirus, toxoplasmosis, human immunodeficiency virus (HIV); rubella; hepatitis A and B viruses; human herpesviruses 6, 7, and 8; and adenovirus. Pharyngitis, lymphadenopathy, hepatitis, and splenomegaly tend to be more common and more severe in EBV-induced IM.[21–26]

The incubation period for IM is approximately 4 to 6 weeks.[27–29] Infection often is heralded by 3 to 5 days of mild headache, malaise, and fatigue. Major clinical manifestations include fever, sore throat or pharyngitis, and lymphadenopathy. Hepatosplenomegaly, jaundice, and rash also can be present.[30] Recurrence is rare.[31]

Body temperature usually rises to 39.4°C and gradually falls over about 6 days. In severe cases, temperature can remain >40°C for 2 weeks or longer.[32,33]

Generalized lymphadenopathy is a hallmark of IM. Involvement of anterior and posterior cervical nodes is most common. Enlarged nodes usually are single, firm, tender, 2 to 4 cm in diameter, and not matted. Massive mediastinal and hilar lymph node enlargement leading to airway obstruction can occur. Mesenteric lymphadenopathy can mimic acute appendicitis symptoms. Lymphadenopathy gradually subsides over days to weeks.[32,33]

Pharyngitis can be indistinguishable from that caused by group A streptococci. The tonsils are enlarged, erythematous, and covered with exudate in more than 50% of cases. Petechiae appear on the palate, characteristically at the junction of the hard and soft palate, between days 5 and 17 of illness in up to 25% of patients.[32–34]

Moderate enlargement of the spleen occurs in about 20% of cases between the second and third weeks of illness and usually is asymptomatic.[35] After splenomegaly is detected, repeated splenic examination should be avoided because of the rare possibility of precipitating splenic rupture.[36] Splenic rupture, leading to hemorrhage, shock, and even death, can follow trauma or can occur spontaneously (1 per 500 to 1 per 1600 cases of IM).[37,38] Splenic rupture should be suspected in any patient with IM and abdominal pain, especially if there are signs of peritoneal irritation, shock, tachycardia, or shoulder pain.[39] Most cases of splenic rupture occur within 3 weeks of the diagnosis of IM,[40] although rupture can occur as late as 7 weeks into the illness.[10,41] Splenic infarction also has been reported.[42]

Hepatomegaly is present in 10% to 35%,[35] hyperbilirubinemia (typically direct) in up to 25%, and moderately elevated serum concentrations of hepatic transaminases in more than 65% of patients with IM.[35,43] Hepatitis can be associated with anorexia, nausea, and vomiting.

An exanthem occurs in about 5% to 20% of cases.[32–34,44–46] The rash usually is located on the trunk and arms; rarely, palmar dermatitis occurs.[47] Rash appears during the first few days of illness, lasts 1 to 6 days, and can be erythematous, macular, papular, or morbilliform. Sometimes an urticarial or scarlatiniform eruption or acrocyanosis is observed.[48–51] Rarely, the rash is petechial, vesicular, umbilicated, or hemorrhagic.[52] Rashes can resemble those of Gianotti-Crosti syndrome and secondary syphilis.[53,54] Eyelid edema occurs in up to 50% of patients, and presternal edema is not infrequent.[34]

In 1967, Pullen and colleagues[55] and Patel[56] observed an increased incidence of rash in hospitalized patients with IM who received ampicillin. The copper-colored exanthem is mainly over the trunk but can progress into an extensive, confluent, maculopapular pruritic eruption that includes the palms and soles. It usually occurs within 3 days of administration and can persist for up to 1 week, with subsequent desquamation. The rash also has been reported with other antibiotics, occurring in ≥30% of patients with IM treated with antibiotics; however, the magnitude of the association has recently been questioned.[10,57–59] Exanthems do not represent hypersensitivity to the antibiotic, which can be used safely when the infection subsides.[60–63]

Paroxysmal cough and radiographic findings of patchy alveolar and interstitial pneumonia develop in a small percentage of patients. Pleural effusion and empyema have also been reported.[64,64a]

Neurologic complications occur in 1% to 5% of cases of IM.[10] Meningoencephalitis is most common.[65] Other reported neurologic complications include aseptic meningitis, Guillain-Barré syndrome, optic neuritis, cranial nerve palsy, transverse myelitis, acute cerebellitis (ataxia or cognitive syndromes), dysautonomia, subacute sclerosing panencephalitis, peripheral neuritis, optic neuritis, psychosis, Parkinson-like syndrome, acute disseminated encephalomyelitis, and central nervous system (CNS) lymphoma.[66–70] These can occur as the singular manifestation of EBV or in association with typical IM.[71]

Hematologic complications generally are mild and occur in about 25% of cases.[10] Transient thrombocytopenic purpura and hemolytic anemia are most common.[72] Rare hematologic complications include aplastic anemia, agranulocytosis, agammaglobulinemia, hemolytic uremic syndrome, and disseminated intravascular coagulation.[10]

Unilateral or bilateral orchitis lasting 2 to 4 weeks and scrotal edema can occur. Renal insufficiency can be present in up to 15% of cases, but renal complications occur <2% of the time and include interstitial nephritis, acute renal failure, and glomerulonephritis.[73–74a] Electrocardiographic abnormalities, as well as pericarditis and myocarditis, have been reported.[75] Endocrinopathies include thyroiditis and polyglandular syndrome.[76,77] Arthritis, pancreatitis, proctitis, ocular involvement, lacrimal gland inflammation, genital ulcerations, necrotizing epiglottitis, hyperuricemia, cholecystitis, extrahepatic biliary obstruction, and hydrops of the gallbladder also have been observed.[78–87]

Death from IM in previously healthy individuals is rare. In a review of the literature from 1932 to 1970, only 20 deaths were attributable to IM. Causes of death, in decreasing frequency, included neurologic complications, secondary infections, splenic rupture, hepatic failure, and myocarditis. Mortality rate was estimated to be less than 1 per 3000 cases.[88]

Laboratory Findings and Diagnosis

IM usually is diagnosed on the basis of typical clinical features, hematologic abnormalities, and a positive heterophil antibody agglutination test. Antibodies to specific EBV antigens can be used to confirm the diagnosis. Younger children often experience primary EBV infection in the absence of characteristic symptoms, hematologic abnormalities, and heterophil antibody response; a specific antibody response to EBV antigens is present, however.[89,90] Histology of lymph nodes can resemble that of a lymphoma.[91]

During the first week of illness, leukopenia or leukocytosis can be so prominent that leukemia is suspected. Absolute increase in the number of atypical lymphocytes is characteristic during the second week of illness. Atypical lymphocytes (Downey cells) are a hallmark of IM. Cells vary markedly in size and shape, and after Wright staining, the cytoplasm is dark blue and vacuolated, with a foamy appearance. Nuclei are round, bean-shaped, or lobulated and contain no nucleoli. Presence of >10% atypical lymphocytes is characteristic, although not specific, for IM.

Serologic Response

The heterophil antibody is a lymphocytotoxic, principally immunoglobulin M (IgM), which appears during the first or second week of illness and gradually disappears over 6 to 8 months. Differential absorption increases specificity for the diagnosis of EBV infection. Typically, serum from patients with IM causes agglutination of sheep red blood cells after absorption with guinea pig kidney antigens, but not after absorption with beef red blood cells. Rapid heterophil slide tests show a high correlation with standard Paul-Bunnell heterophil test results,[91a,92] and the specificity of the test for EBV infection is high (>95% in some studies). False-positive heterophil test results can occur with rubella, cytomegalovirus, adenovirus, hepatitis C, HIV, malaria, systemic lupus erythematosus, leukemia, and lymphoma.[92–96] Sensitivity ranges between 70% and 90% and is lower in younger patients and in Asians.[97]

The first antibodies produced during the course of primary EBV infection are IgM antibodies directed against VCA (Fig. 208.3), which are transient, usually disappearing in 4 to 8 weeks,[10] whereas

IgG antibodies to VCA persist for life. Antibodies against the EA complex appear later in the course of acute infection and usually disappear after 6 months; however, low levels of antibody (mainly to the R component) of the EA complex can be detected in up to 20% of healthy individuals for years after IM.[98]

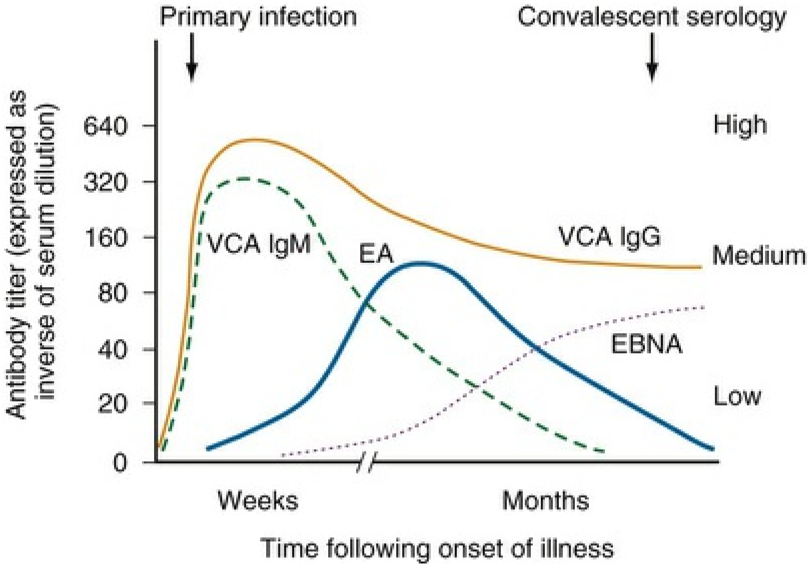

FIGURE 208.3 Idealized time course for the development of antibody to different Epstein-Barr virus antigens after primary infection with the virus. EA, early antigen; EBNA, Epstein-Barr nuclear antigen-1; IgG, immunoglobulin G; IgM, immunoglobulin M; VCA, viral capsid antigen.

Antibodies against the EBNA complex usually are detectable only after 1 to 6 months, rising during convalescence, unlike antibodies to VCA and EA. All late convalescent sera from healthy, previously infected individuals contain high titers of antibodies against EBNA. Thus the presence of IgG antibody against VCA and the absence of antibody to EBNA are diagnostic of primary EBV infection. IgM antibody to VCA also denotes acute infection; however, this assay is technically difficult and can yield false-positive reactions in the presence of rheumatoid factor. Extremely elevated antibody to VCA or EA in the presence of antibody to EBNA is compatible with reactivated EBV infection (Table 208.1).[99–100]

TABLE 208.1

Typical Serologic Findings Related to the Stage of Epstein-Barr Virus Infection

Stage of Infection	Presence of Antibody
Primary	VCA IgM or IgG (usually high) ± EA (usually high), no (or low) EBNA
Convalescent/past	VCA IgG ± EA (low), EBNA (high)
Reactivation	VCA IgG (high) ± EA (high), EBNA

EA, early antigen; EBNA, Epstein-Barr nuclear antigen; IgG, immunoglobulin G; IgM, immunoglobulin M; VCA, viral capsid antigen.

Autoantibodies, including antinuclear antibody, rheumatoid factor, a false-positive reagin test for syphilis, and false-positive mumps and rubella IgM tests, occur occasionally during IM.[101,102] Some EBV-induced antibodies can have clinical importance. For example, IgM and IgG antiplatelet antibodies can be associated with thrombocytopenia,[103] and anti-I,[104] anti-i, and anti-HLA class I antibodies can cause severe hemolytic disease.[104,105] Hypogammaglobulinemia or isolated IgA deficiency also can occur.[106,107]

Detection of Epstein-Barr Virus

Detection of EBV usually is not required for making a diagnosis of acute IM in immune competent individuals; in most cases, serology remains the standard for diagnosis. Nevertheless, several techniques are available for direct detection of EBV.

The immortalization assay assesses the ability of patient's specimen (saliva, peripheral blood, lymph node tissue) to cause lymphoblastic transformation of laboratory-cultured lymphocytes (usually umbilical cord cells). This test is time-consuming (6 to 8 weeks) and requires specialized tissue culture facilities.

Immunofluorescence or immunoperoxidase staining or Western blot or immunoblot of proteins can be used to demonstrate latent viral antigens (e.g., EBNA) in tissue. The most specific method for demonstrating EBV in pathologic material is nucleic acid hybridization. Two techniques are currently used: (1) in situ hybridization, which identifies cells that contain EBV nucleic acid; and (2) polymerase chain reaction (PCR), which amplifies a segment of DNA. PCR generally is more sensitive than immortalization assays.[108]

In many cases of acute infection and in some asymptomatic, healthy individuals with primary infection, EBV DNA can be detected in blood for up to 50 days by PCR. EBV DNA load in the blood and $CD8^+$ lymphocytosis correlate with severity of disease; median amounts of EBV DNA in the blood during acute IM are 10^3 to 10^4 genome copies/mL.[109–114]

In situ hybridization for the abundant EBV-encoded small RNAs (EBERs, which are expressed in latency[115] and play multiple roles in the growth transformation of B lymphocytes[116]) is a specific and sensitive technique for detecting EBV-infected cells in pathologic specimens. Often the number and type of infected cells can be determined.[117]

Treatment

IM is a self-limited illness; treatment is supportive. Bed rest is indicated in the acute stage of disease. Most patients resume normal activities in 2 to 3 months, although about 10% of individuals are still symptomatic at 6 months.[10] Acetaminophen and saline gargles can be used to control the discomfort caused by enlarged lymph nodes and pharyngitis; in severe cases, codeine or meperidine may be required.

A Cochrane review concluded that there was insufficient evidence to recommend corticosteroid therapy for symptomatic relief of uncomplicated IM.[118] Although often prescribed,[119] caution is warranted because of reports of neurologic complications and secondary bacterial infections after corticosteroid use.[120,121] Corticosteroid therapy should only be considered for the treatment of severe complications such as obstruction of the airway or thrombocytopenic purpura.

Contact sports should be avoided until patients are fully recovered and the spleen is not palpable at an examination at least 3 to 4 weeks after onset of illness.[41] Splenic enlargement can occur after the first or diagnostic visit.

Acyclovir and ganciclovir act only on the lytic phase of EBV replication. Ganciclovir also can inhibit EBV-induced B-lymphocyte immortalization,[122] and its antiviral effect is more potent than that of acyclovir or valacyclovir.[123,124]

Parenteral administration of acyclovir to patients with acute IM reduces the replication of oropharyngeal EBV; however, there is little effect on clinical course.[125,126] A randomized, double-blind, placebo-controlled treatment trial of oral acyclovir plus prednisolone in 94 adolescents and young adults showed no significant effect of treatment.[127] One small, unblinded, non–placebo-controlled trial using a nonvalidated symptom questionnaire showed a trend toward clinical improvement with valacyclovir use.[124] In cases of severe EBV-related complications (e.g., encephalitis) or in the immunocompromised host, treatment often is used based on anecdotal data and expert opinion.[128]

Pathogenesis and Disease in Immunosuppressed Children

After primary infection, EBV persists in about 1 in 10^5 to 1 in 10^6 B lymphocytes in a latently infected, immortalized form. These infected B cells periodically undergo lytic replication to produce cell-free virus. Neutralizing antibodies (to viral envelope glycoprotein, gp350[129]) and cytotoxic lymphocytes (which include NK lymphocytes and $CD8^+$ cytotoxic T lymphocytes directed mainly against EBNA-3[129,130]) limit primary infection and keep the immortalized, EBV-infected B-lymphocyte pool in check. Cytotoxic T lymphocytes and NK lymphocytes exert effect at least partly through the secretion of a protein termed *perforin,* which causes target cells (i.e., EBV-infected B lymphocytes) to undergo apoptosis.[131] $CD4^+$ T lymphocytes also may play a role in inhibiting B lymphocytes recently infected by EBV.[132] If the immune response is dysfunctional, the normally small pool of EBV-infected cells can expand, perhaps allowing an EBV-activated B lymphocyte to transform into a lymphoma cell (see Fig. 208.2).

Posttransplantation Lymphoproliferative Disorder

Patients undergoing solid organ transplantation (SOT) or bone marrow or hematopoietic stem cell transplantation (HSCT) can develop posttransplantation lymphoproliferative disorder (PTLD) as a result of immunosuppression. In SOT patients, immunosuppression is due to medications required to prevent rejection. In HSCT patients, immunosuppression begins with the conditioning regimen. The greater the immunosuppression, the greater is the risk for developing PTLD. In SOT patients, therapies associated with greater risk include calcineurin inhibitors (cyclosporine and tacrolimus [FK-506]). For HSCT patients, risk factors include the use of antibodies against T lymphocytes (especially antithymocyte globulin or anti-CD3 antibody) or use of an HLA-mismatched donor.

In SOT patients, EBV-naiveté before transplantation (especially when receiving an organ from an EBV seropositive donor) presents a 5- to 10-fold higher risk for PTLD. Unfortunately, children and adolescents are more likely to be EBV naïve before transplantation, and, because of their scarcity, it is not feasible to use only EBV-naïve donors for EBV-naïve recipients.

The risk for developing PTLD is greatest (50%–90%) in the first year after transplantation.[133] Because HSCT recipients usually have immune reconstitution within 1 year of transplantation, PTLD rarely occurs >1 year after HSCT. In SOT patients, PTLD can occur many years after transplantation.

Most PTLD lesions occurring early after transplantation originate from B lymphocytes, and most cells are EBV positive. In contrast, only 15% to 40% of lesions occurring >1 year after SOT are EBV positive, and some originate from T lymphocytes or NK cells.[134] PTLD can range from a self-limited IM-like illness to a fatal illness characterized by solid tumors that usually resemble large cell non-Hodgkin lymphoma (NHL). A substantial number of PTLD tumors developing in solid organ recipients involve the CNS, gastrointestinal tract, or grafted organ.[129]

The histology of PTLD ranges from plasmacytic, hyperplastic, or polymorphic lesions to lesions that can be monomorphic or lymphomatous. Plasma cell hyperplasias usually are polyclonal and often regress with decreased immunosuppression. However, polymorphic PTLD lesions can contain subpopulations of genetically monoclonal cells, which are less likely to regress with tapering immunosuppression, and even frank lymphomas occasionally regress when immunosuppression is reduced.[135] Recurrences, which develop in about 5% cases, are more likely to be clonal and aggressive than the original lesion.[136]

The diagnosis of PTLD can be difficult. Serologic evidence of disease includes a primary or reactivated EBV response with or without decreasing EBNA titers.[137,138] Virologic evidence of disease includes demonstrating the presence of EBV within the lesion by PCR or in situ hybridization. A definitive diagnosis of PTLD only can be made histologically.[139]

Increasing levels of EBV DNA in the peripheral blood, as measured by PCR, correlate with the development of PTLD in both SOT and HSCT patients.[140] Wide variability in reported EBV load, depending on the units and the laboratory used, precludes the establishment of cutoff limits that are generalizable.[141] Knowledge of the ranges of EBV load that correlate with disease for each laboratory is crucial.

There is no proven method to prevent PTLD. Although not everyone with high EBV loads in the blood develops PTLD,[142,143] most transplantation physicians trend EBV loads to determine which patients are at highest risk for PTLD, so that diagnostic testing can be performed as early as possible.[144] Some retrospective data suggest that ganciclovir or acyclovir therapy can reduce the risk for PTLD. This effect could be due to direct activity against lytic EBV or to prevention of cytomegalovirus infection, which may be a risk factor for PTLD.[145] Retrospective data also suggest that CMV hyperimmune globulin can prevent PTLD in the first year following kidney transplantation.[145a] Pre-emptive management, which includes decreasing immune suppression plus use of rituximab or cytotoxic T-lymphocytic infusions, or both, has been evaluated in transplant recipients with increased EBV loads.[146–152] Prophylactic rituximab has been used as well.[152a,152b]

Treatment of PTLD is not optimal. Recent estimates of mortality range from 10% to 35% and may be higher in adolescents and in those with multiple sites of disease or CNS involvement, in patients with T- or NK-cell disease, or in EBV-negative or CD20-negative disease.[133,153,154] Although no controlled trial is available to guide therapy, attempts to standardize management are based on large case series.

Reduction of immunosuppression[135] is the first step in treatment for PTLD in SOT patients, despite the risk for rejection.[129] Usually azathioprine and mycophenolate mofetil are discontinued, and doses of cyclosporine, tacrolimus, and prednisone are halved.

Use of 4 weekly infusions of the anti-CD20 monoclonal antibody, rituximab, has been examined systemically in patients failing reduction of immunosuppression.[144,155] Normal B lymphocytes and most B-lymphocyte malignancies express CD20. By eliminating all $CD20^+$ lymphocytes within days, rituximab eliminates most PTLD lesions. The complication rate after rituximab therapy is low (although rare, fatal complications such as hepatitis B reactivation have been reported[155a]), whereas the PTLD remission rate is about 70%.[156,157] Rituximab does not penetrate the CNS well; thus CNS lesions are unlikely to respond without intrathecal administration.[158,159] The recurrence rate following rituximab therapy is about 20%, usually occurring after the biologic effect of rituximab wanes (i.e., after about 6 months) or due to the development of PTLD lesions that are CD20 negative.[160,161]

In patients who fail rituximab therapy, chemotherapy has about a 75% response rate, but with a rate of toxicity of about 25%.[162–164] Low-dose chemotherapy (with or without rituximab) also has been used.[165] Antiviral agents generally are not recommended for treatment of PTLD.[144] For treating focal PTLD tumors, local radiation or surgery, or both, may be useful.[166]

Disease Associated With Acquired Immunodeficiency Syndrome

Four major EBV-associated conditions can develop in patients with HIV infection: lymphocytic interstitial pneumonitis (LIP), NHL,; (3) oral “hairy” leukoplakia, and leiomyosarcoma. These conditions have become uncommon since the advent of combination antiretroviral therapy (cART).[167]

Lymphocytic Interstitial Pneumonitis.

Before the AIDS epidemic, LIP usually was observed only in adults with immunologic abnormalities.[168] LIP in children with AIDS is associated with generalized lymphadenopathy and parotitis and may be part of a more diffuse, predominantly $CD8^+$ lymphoproliferative process, in which dominant manifestations are bilateral and diffuse reticulonodular densities are seen on chest radiography.[169–171] LIP occurs in about 30% of untreated HIV-infected children.[172,173] Diagnosis is confirmed by lung biopsy.

EBV DNA is detected in the lungs of approximately 80% of children with LIP.[174–176] In a case-control study, all children with LIP had evidence of primary or reactivated EBV infection compared with significantly fewer matched, HIV-infected control subjects.[177] In a prospective study, LIP developed in 1 of 18 HIV-infected children 7 months after primary EBV infection.[178] LIP is uncommon in adults with AIDS likely because LIP is a manifestation of primary EBV infection. LIP has been reported to regress with acyclovir therapy, although corticosteroids may be more effective.[179] Resolution after cART also is reported.[171,180] LIP is not a lymphoma and has a better outcome than other opportunistic infections in untreated HIV-infected children.

Non-Hodgkin Lymphoma.

In the general population, Hodgkin disease is more prevalent than NHL. In immunocompromised individuals, however, NHL is more common. NHL in patients with AIDS is more aggressive, more likely to be manifest at extranodal sites, and more likely to be composed mainly of oligoclonal B lymphocytes.[181–188]

EBV is detected in at least one half of NHL lesions in patients with AIDS. EBV load correlates with cancer risk in pediatric HIV-infected patients with CD4 counts >200/mm^3. More than 90% of CNS lymphomas are EBV associated.[189,190] PCR of cerebrospinal fluid has been used to distinguish AIDS-associated CNS NHL from other CNS mass lesions; this test is sensitive but not specific.[191]

Oral Hairy Leukoplakia.

A form of oral leukoplakia was recognized in HIV-seropositive men who had sex with men, beginning in 1984. Oral leukoplakia occurs rarely in children[192] and manifests on the lateral surface of the tongue with lesions resembling flat warts.[193] The presence of EBV DNA and antigens in biopsy material, documentation of lytic EBV DNA replication in epithelial cells of lesions,[194] and regression of lesions after treatment with acyclovir support an EBV etiologic role.[194,195] EBV DNA also has been identified in esophageal ulcers in HIV-infected patients, the pathology of which resembles oral hairy leukoplakia.[196]

Leiomyosarcoma.

Leiomyosarcomas are malignant cancers of smooth muscle and are rare in childhood. However, cases associated with EBV have been seen mainly in children and young adults with AIDS and in transplant recipients. There is one case report in a child with NK cell deficiency as well. The tumors are monoclonal, biclonal, or oligoclonal and often are multifocal. Serologic data revealed a reactivated EBV infection in 1 of 3 patients with AIDS and in 9 of 9 transplant recipients who were EBV naïve before transplantation. Most reported patients also had a high EBV load, and leiomyosarcoma can be associated with PTLD.[197–199] Surgery is the mainstay of therapy, especially with focal disease, although reduction of immunosuppression, antiviral medication, rituximab, and radiation therapy also have been used, sometimes in combination.[199] Prognosis is poor, with mortality in >50% of transplant recipients.[199]

X-Linked Lymphoproliferative Syndrome, Infection-Associated Hemophagocytic Syndrome, and Chronic Active Epstein-Barr Virus Infection

X-linked lymphoproliferative syndrome (XLPS), infection-associated hemophagocytic syndrome (IAHS), and chronic active EBV infection (CAEBVI) are clinically overlapping syndromes associated with EBV infection. All are related to the inability of NK or cytotoxic T lymphocytes, or both, to regulate EBV proliferation. All three can be classified under the rubric of hemophagocytic lymphohistiocytosis (HLH), which is a disorder of NK cells, cytotoxic T lymphocytes, and macrophages and characterized by hypercytokinemia ("cytokine storm").[200]

HLH was first described in 1939, recognized as possibly being familial in 1952, and first associated with viral infections in 1979[201] (see Chapter 12). Some forms of HLH are genetic in origin. Others are triggered by infection, malignancy, or rheumatologic conditions. It is suspected that there are as yet largely unknown, perhaps more subtle predisposing genetic factors to these acquired forms as well. Both forms can be associated with EBV.[200] In some of these conditions, EBV infects T or NK lymphocytes, rather than B lymphocytes.

X-Linked Lymphoproliferative Syndrome

Rare individuals with an X-linked genetic predisposition are incapable of mounting a normal immune response to primary infection with EBV. Thus this disorder has *both* a known genetic mutation and a known extrinsic trigger (EBV infection). Up to 90% of patients with XLPS have evidence of hemophagocytosis.[200,202,203]

A progressive *proliferative* response develops in about 60% of individuals affected by XLPS (Box 208.1). The cause of death in these individuals is usually liver necrosis secondary to infiltration of lymphoid cells. Pathologic examination reveals widespread mononucleosis-like changes in two thirds of patients and malignant B-cell lymphoma, usually of the Burkitt type, in one third of patients. Approximately one third of patients with XLPS survive the initial EBV infection, and an aproliferative disease develops. Findings in these patients include hypogammaglobulinemia, aplastic anemia, agranulocytosis, increased susceptibility to bacterial infection, and the development of malignancies.[202,203]

Box 208.1

Major Manifestations of X-Linked Lymphoproliferative Syndrome

Proliferative

Fatal infectious mononucleosis

Malignant lymphoma

Associated with hemophagocytic syndrome

Aproliferative

Hypogammaglobulinemia

Aplastic anemia

Agranulocytosis

Associated with bacterial infections, late malignancies

Most patients with XLPS have normal responses to bacterial and other viral infections of childhood and have normal cell-mediated immune responses and T- and B-lymphocyte numbers.[204] Immunologic evaluation of patients with XLPS during the course of their acute EBV infection reveals exaggerated $CD8^+$ T-lymphocyte activity against EBV-infected B lymphocytes. In survivors, a global deficiency in immunoglobulin production, T-lymphocyte and NK-cell function is observed, and almost all survivors fail to produce or lose antibody to EBNA and have abnormalities in VCA antibody production, suggesting an inability to regulate primary EBV infection.[202] Perhaps because EBV is the first lymphoproliferative challenge that many individuals face, and the only human pathogen that is exclusively B-cell tropic, the subtle immune dysregulation in patients with XLPS is not manifest until they experience primary EBV infection.

There are two known gene defects that cause XLPS. The SAP (signal lymphocyte activation molecule [SLAM]-associated protein) genetic defect, found in about 80% of patients with XLPS, is a defect in an inhibitory T-lymphocyte signaling pathway important for T-lymphocyte development and function.[202,203] SAP normally is important for the control of T-lymphocyte activation, NK-cell activation and cytotoxicity, and memory B-lymphocyte development[203,205] (see also Fig. 208.2). Untreated, about 75% of boys with the SAP defect die within a month of primary EBV infection.[206] It has been postulated that an apoptotic defect of cytotoxic T lymphocytes might lead to the fatal IM phenotype because of an inability to downregulate the cytotoxic T-lymphocyte response against EBV, whereas an apoptotic defect of B-lymphocyte subpopulations might lead to B-cell lymphomas.[203] A second genetic defect (X-linked inhibitor of apoptosis [XIAP]) has been observed in most of the remaining patients with XLPS.[207] Lymphomas have not been reported in these patients, perhaps explaining some of the phenotypic heterogeneity of XLPS, although an exact genotype-phenotype correlation and an understanding of the pathophysiology of both forms of XLPS remain incomplete. Seventeen percent of patients with XIAP deficiency have been reported to suffer from hemorrhagic colitis, which is not reported in SAP-deficient patients.[190] Flow cytometry is often used for diagnosis.[208] Other, rare related syndromes have been reported recently in which patients have a heightened susceptibility to EBV-associated lymphomas.[208a]

Therapeutic options for XLPS are limited. Patients with proliferative responses often are treated with regimens similar to those used for IAHS.[209] Definitive therapy is stem cell transplantation; outcome is improved after transplantation for all categories of illness, especially in patients with SAP deficiency and a history of HLH.[200,202] Boys who are discovered before acquiring infection with EBV have been treated with monthly immune globulin intravenous (IGIV) therapy to prevent acquisition of EBV and occasionally have undergone pre-emptive transplantation or have been treated with rituximab, corticosteroids, immunoglobulin, and ganciclovir after acquiring primary EBV infection.[210,211] If HSCT is not undertaken immediately, a donor should at least be identified and the patient followed carefully for signs of disease progression. The prospect of an EBV vaccine to prevent primary infection is still years away.[212,213]

Infection-Associated Hemophagocytic Syndrome

Familial HLH is a rare genetic syndrome associated with defects in the pro-apoptotic perforin (or related granulocyte-mediated cytotoxic) gene pathways and with excessive and persistent activation of macrophages and hypercytokinemia. Left untreated, the 3-year survival rate is about 10%[131,214,215] (see Chapter 12).

IAHS is thought to be a secondary, acquired form of HLH, although it is likely that it, too, has a genetic basis. The most common infectious trigger of IAHS is primary EBV infection. A similar syndrome can be triggered by malignancies or rheumatologic disorders. When triggered by a rheumatologic disorder, HLH is referred to as *macrophage activation syndrome*.[200] Patients diagnosed with IAHS can have compound heterozygous genetic mutations, promoter variants, or missense mutations of apoptotic pathways.[216,217] Children diagnosed with familial HLH often are younger (<1 year of age) than those diagnosed with IAHS (or other acquired forms of HLH) (see Box 208.2).[200] In children <3 years of age, a serum ferritin level >10,000 ng/mL is about 95% sensitive and specific for diagnosing IAHS, and a normal level has a high negative predictive value for ruling out IAHS.[217a]

Box 208.2

Hemophagocytic Lymphohistiocytosis

Familial/Homozygous Genetic Causes

- Perforin or other gene mutations; onset <1 year of age in 70%–80%
- Decreased SAP or XIAP (X-linked lymphoproliferative syndrome; usually triggered by EBV); mean age at diagnosis 5 years

Acquired/Secondary/Heterozygous or Missense Genetic Causes

- Triggered by infection (infection-associated hemophagocytic syndrome), EBV responsible 75% of the time; mean age at diagnosis 4 years
- Triggered by rheumatologic (macrophage activation syndrome) and malignant conditions

EBV, Epstein-Barr virus; SAP, signal lymphocyte activation molecule (SLAM)-associated protein; XIAP, X-linked inhibitor of apoptosis.

When triggered by EBV, IAHS appears to be due to macrophages reacting against EBV-infected CD8$^+$ T lymphocytes.[218] Etoposide, which reduces macrophage activation, and dexamethasone, with or without cyclosporine, are used to treat HLH. The 5-year survival rate for presumed nonfamilial cases is 55% ± 5%. Definitive therapy and potential cure of familial HLH require stem cell transplantation[219]; presumably, as more genetic causes are discovered, the pathophysiology becomes better understood, and the techniques for HSCT are improved, the indications for HSCT will expand.

Chronic Active Epstein-Barr Virus Infection

CAEBVI has been reported mainly in Asians and appears to have two subtypes: a T-lymphocyte form and an NK-cell form, depending on which cells are infected with EBV.[220] Clinically, patients with CAEBVI have chronic or recurrent mononucleosis-like symptoms, including fever, lymphadenopathy, and hepatosplenomegaly, for at least 3 months. Hepatitis, pancytopenia, uveitis, interstitial pneumonitis, skin manifestations (e.g., photosensitivity, hypersensitivity to mosquito bites), sicca syndrome, neuropathy, cardiomyopathy and carditis, neutropenia, eosinophilia, thrombocytopenia, and hypergammaglobulinemia or hypogammaglobulinemia also can occur; a similar cytokine storm as previously described can be present.[221] The disease is clonal and occasionally can mimic leukemia.[222] Rarely, coronary artery ectasia or aneurysms are observed.[223] Patients have prolonged, severe, relapsing, and often fatal courses. Death can be associated with respiratory failure secondary to interstitial pneumonia or with diffuse T-lymphocyte infiltrate, lymphoma, or hemophagocytic syndrome.[224,225] Distinguishing clinically between CAEBVI and IAHS is difficult. A rare, chronic blistering photodermatosis, hydroa vacciniforme, also can be a part of this syndrome.[223a]

Patients with CAEBVI have markedly abnormal EBV serologic responses, such as extremely high levels of antibody to the EA and VCA complexes and low or absent antibody to EBNA. Some patients have selective absence of antibody to EBNA-1.[226] Impaired cytotoxic T-lymphocyte responses against EBV-infected NK cells are reported.[227] EBV loads typically also are extremely high, especially in patients with complications. Elevated EBV load in cerebrospinal fluid in patients with CNS involvement is reported.[228–231] Before EBV infection, there is no clinical evidence of an immunologic abnormality. These patients do not have the gene defect associated with XLPS,[232] although there is a case report of a patient with CAEBVI and a perforin gene defect.[233] In general, a different apoptotic pathway (Fas[CD95]/Fas ligand) seems to be involved in this disease.[234]

The NK-cell form of CAEBVI is characterized by high EBV DNA loads, high serum IgE level, NK-cell lymphocytosis, and hypersensitivity to mosquito bites. The T-lymphocyte form of the disease is associated with anemia and a poor prognosis. In contrast to IAHS, mainly non-$CD8^+$ T lymphocytes are involved in CAEBVI.[235] Other poor prognostic signs are age >8 years and platelet count <12,000/mm^3 on presentation.[236]

Several families have been described in which this syndrome has occurred in multiple members.[237] Stem cell transplantation[238] or autologous cytotoxic T-lymphocyte infusions are the most effective therapies, although mortality remains high (20%–50%)[239];

chemotherapy also has been used.[240]

Chronic active EBV infection must not be confused with chronic fatigue syndrome (CFS).[241] In CFS, few, if any, objective signs of illness exist. EBV serologies are not helpful for diagnosis,[242] despite the finding that a few patients have elevated antibody titers to EA[243] and may lack antibody to EBNA-1.[226] Six months after IM, about 10% of adolescents will meet the criteria for CFS; whether severity of illness, autonomic dysfunction, or other factors play a role in prolonged recovery from IM is unclear.[244–249]

Congenital Infection

Rare infants with birth defects attributed to congenital infection following maternal primary EBV infection have been reported. One infant had bilateral congenital cataracts, cryptorchidism, hypotonia, and mild micrognathia. A "celery stalk" appearance of long bones was noted radiographically, similar to that seen with congenital rubella.[250] Nevertheless, a prospective study of more than 4000 pregnant women failed to document intrauterine EBV infection.[251] Another report described nearly 700 pregnant women with serologic evidence of EBV infection during pregnancy. Pregnancies were several times more likely to result in early fetal death, premature labor, or delivery of an infant who became ill soon or after birth[252]; however, the association of these conditions with EBV infection is unknown. A comprehensive review of this topic has been published.[253]

Human Herpesvirus 8 (Kaposi Sarcoma–Associated Herpesvirus)

Mary T. Caserta

In 1872, Moritz Kaposi, a Hungarian dermatologist, first described in five men an aggressive, pigmented, multicentric sarcoma of the skin that disseminated to multiple sites.[1] It was rare and received little attention until similar lesions were observed in African children and adults, and subsequently when found in association with human immunodeficiency virus (HIV) infection in the 1980s. Although the cause of Kaposi sarcoma (KS) was suspected to be infectious, it was not confirmed until 1994 when Chang and colleagues[2] isolated two novel DNA fragments with homologies to two oncogenic γ-herpesviruses from a sarcoma in an HIV-infected patient. This led to classification of human herpesvirus-8 (HHV-8), also referred to as Kaposi sarcoma–associated herpesvirus (KSHV), as a lymphotropic γ-herpesvirus. Except for the endemic and epidemic forms observed primarily in Africa, HHV-8 disease rarely occurs in children.

Description of the Pathogen

HHV-8 is the only human γ2-herpesvirus. Epstein-Barr virus (EBV), a γ1-herpesvirus, is the most closely related human virus. HHV-8 is a large, double-stranded, enveloped DNA virus. Its genome has a central unique region of about 140 kb, encoding the known open reading frames and flanked by terminal repeat sequences that contain signals for packaging and cleavage.[3,4] The genome contains micro RNAs and several cellular homologs related to human oncogenes, cytokines, and chemokines. These molecules inhibit tumor suppressor pathways by affecting control of cellular growth and inhibition of apoptosis as well as promoting inflammation and angiogenesis.[5,6]

HHV-8 infects multiple cell types, with evidence suggesting that glycoprotein B (gB) is the virus attachment protein.[7] Additionally, DC-SIGN (dendritic cell–specific intercellular adhesion molecule-3–grabbing nonintegrin, also known as CD209) and its isomer DC-SIGNR have been identified as cell receptor molecules on dendritic cells, activated macrophages, and B lymphocytes and on endothelial cells, respectively.[7] After initial infection, the HHV-8 genome persists as covalently closed episomal circles, establishing lifelong latent infection. Monocytes and B lymphocytes are the major reservoirs.[7,8] HHV-8 can be propagated in cell cultures, but most patients are latently infected and lytic infection must be induced.[8]

Epidemiology

In contrast to other herpesviruses, HHV-8 does not cause ubiquitous worldwide infection. Its prevalence mirrors the incidence of KS.[9] Seroprevalence studies show substantial geographic variation, with the highest rates in sub-Saharan Africa, ranging from 20% to >60%.[10–14] In Cameroon, Ghana, Uganda, Zambia, Tanzania, and among indigenous groups in the Amazon of Brazil, 30% to 60% of children <10 years of age are seropositive.[11–13,15,16] Seroprevalence is 6% to 20% in most Mediterranean countries and are lowest, 0% to 5%, in northern Europe, the United States, Latin America, and Asia.[9] Seropositivity and disease can vary widely among countries within the same region. Furthermore, high-risk groups exist in countries with low

HHV-8 seroprevalence. For example, in the US, 15% to 40% of men who have sex with men (MSM) are seropositive, with the highest rates occurring among HIV-infected MSM.[10,17] Seroprevalence is not as high among other HIV-infected populations, especially children.[18]

The putative modes of acquisition of HHV-8 include nonsexual and sexual horizontal transmission, vertical transmission, blood transfusions, and organ transplantation.[9,11,13,18,19] In areas with low HHV-8 prevalence, transmission is mainly sexual and predominantly among MSM. In areas with high HHV-8 seroprevalence, transmission appears to be nonsexual, occurring among families and close contacts, with high seropositivity present among children before adolescence and continuing to increase thereafter.[12,13] Secretions, primarily saliva, are likely the major source of infection.[9,13]

Viral DNA is detected most frequently and in highest levels in saliva, but also is in semen and peripheral blood mononuclear cells.[9,20,21] Blood transfusions have been correlated with HHV-8 seropositivity among children from endemic countries, but appear to have no appreciable role in transmission in the US.[19,22,23] No evidence exists for transmission through breast milk.[24] Vertical transmission has been suggested by detection of HHV-8 DNA in the blood of a few neonates.[25]

Clinical Manifestations

HHV-8 has a clear causal role only in KS, primary effusion lymphoma, multicentric Castleman disease, and a KSHV cytokine inflammatory syndrome associated with HIV infection.[26,27] Many diseases have been associated with HHV-8 infection, but not confirmed causally, including multiple myeloma, sarcoidosis, and basal and squamous cell carcinomas in transplant recipients.

Clinical manifestations of HHV-8 infection primarily are associated with KS, a multifocal neoplasm of vascular endothelium.[18,28] KS lesions are vascular, purplish nodules that range from isolated cutaneous lesions to widespread disease involving the lung, biliary tract, and other viscera (Fig. 209.1).

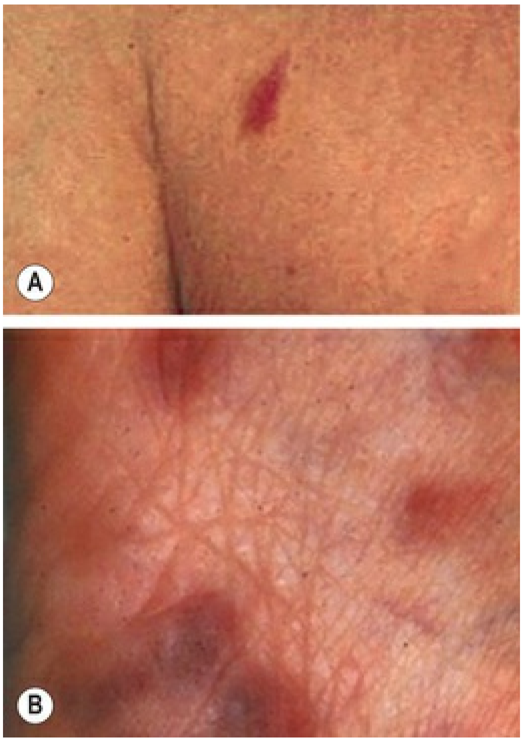

FIGURE 209.1 Kaposi sarcoma lesions of the chest (A) and foot (B). (Courtesy of Susan Cohn, MD, Northwestern University, Evanston, IL.)

HHV-8 infection is a necessary, but not sufficient, factor contributing to the development of KS.[28,29] Four KS variants have been described: classical, endemic/sub-Saharan African, epidemic (AIDS-associated), and immunosuppression-associated forms. The classical type, primarily affecting older men from Mediterranean and eastern European countries, is indolent, involves mainly the skin, and is associated with long survival. The endemic form occurs predominantly in parts of sub-Saharan Africa and affects both adults and children.[18] In some areas of Central Africa, KS is among the most common tumors, causing up to 25% of all childhood malignancies.[18,30] Endemic HIV-negative KS in African children is distinct from the adult form and characteristically is a more aggressive, often fatal, lymphadenopathic disease, usually with no cutaneous manifestations.[31,32] Endemic KS has been reported in children born to consanguineous parents, suggesting inherited immunodeficiency as a possible mechanism of KS disease development in areas of high HHV-8 prevalence.[33]

Epidemic KS associated with HIV usually is aggressive, with widespread cutaneous and visceral involvement, and is associated with a poor prognosis without treatment. Since the advent of combination antiretroviral treatment (cART) for HIV infection, the incidence of KS has declined and the outcome improved substantially.[9,28,34,35] Epidemic KS in children more closely resembles the endemic form, with lymphadenopathy as a prominent feature.[36] Other common sites of involvement include the oral mucosa and the gastrointestinal and respiratory tracts.[18] Immune reconstitution inflammatory syndrome KS may cause worsening signs and symptoms of KS in children newly started on cART and necessitate more aggressive treatment.[18,28] KS associated with immunosuppression not related to HIV most frequently occurs in endemic areas in solid-organ transplant recipients with previous HHV-8 infection.[37]

Descriptions of primary infection are limited but indicate that most are likely asymptomatic. Clinical expression varies geographically and according to comorbidities.[38,39] Among young immunocompetent children residing in endemic areas, primary infection was identified in 7% of those presenting with acute febrile illnesses.[38] Clinical manifestations included fever, upper respiratory tract signs, and a nonspecific maculopapular rash. A mononucleosis-like illness also has been described.[40] Acquisition of primary HHV-8 infection in children following transfusion is associated with increased mortality for 2 to 10 weeks after the event.[22]

Among immunocompromised patients, primary infection often is asymptomatic but sometimes manifests as a febrile illness of varying severity, with lymphadenopathy, splenomegaly, arthralgia, pancytopenia, and occasionally acute onset of KS.[39,41,42]

Diagnosis

Laboratory methods for diagnosing HHV-8 infection are not standardized. Many polymerase chain reaction (PCR) and serologic assays are available, but their sensitivity, specificity, and clinical usefulness vary widely.[39,43,44] However, when combined with histopathology and immunocytochemistry, these tests permit accurate diagnosis of KS and other HHV-8–associated lymphoproliferative disorders.

Serologic tests include indirect immunofluorescence assays to detect latency-associated nuclear antigen and lytic antigens, enzyme immunoassays, and immunoblot assays.[13,44] Their usefulness is dependent on which antigens are detected because gene expression varies among different HHV-8–related entities.[43] Combining several serologic assays generally increases the sensitivity and specificity of detecting infection.[44]

PCR assays can detect HHV-8 in blood and tissue specimens, but results can be confounded by the variable and often low number of HHV-8 genomic copies present in infected tissue and peripheral blood and by the occurrence of asymptomatic viremia.[45] PCR assays have been used to support the diagnosis of HHV-8–associated disorders, detect exacerbations, and help determine prognosis.[45–47]

Management and Therapy

No antiviral therapy is approved in the US for the treatment of HHV-8 infection. The use of cART for HIV infection decreases the incidence of KS and provides treatment benefit in early-stage disease.[28,35,45,46] In addition, ganciclovir and valganciclovir have been shown to decrease the incidence of KS in HIV-infected patients, decrease the frequency and quantity of HHV-8 oral shedding, and be useful as consolidation treatment in patients with HIV-associated multicentric Castleman disease.[20,45,48,49]

Current treatment efforts directed at controlling the lymphoproliferative complications of HHV-8 infections in HIV-infected individuals typically include therapy with cART and traditional chemotherapeutic regimens based on the resources of the region.[49–53]

Acknowledgment

The author acknowledges the substantial contribution of Caroline Breese Hall to previous editions of this chapter. The infectious diseases community recognizes her major contributions to our field and our great sadness in her loss. – Sarah S. Long

Key Points

Epidemiology, Clinical Features, Diagnosis, and Management of Human Herpesvirus 8 Infections

Epidemiology

- Human herpesvirus 8 (HHV-8) is also known as Kaposi sarcoma herpesvirus (KSHV), a lymphotropic γ2-herpesvirus most closely related to Epstein-Barr virus.
- After primary infection, HHV-8 persists as a lifelong latent infection.
- Prevalence of infection mirrors the incidence of Kaposi sarcoma (KS), with notable geographic variability.
- The highest seroprevalence is in sub-Sahara Africa, followed by the Mediterranean and Middle East; the lowest rates are in Europe and North America.
- In areas of low prevalence, high-risk groups, such as men who have sex with men, have increased rates of infection.
- Transmission is thought to be through saliva; young children in endemic areas acquire infection nonsexually from household contacts.

Clinical Features

- HHV-8 causes lymphoproliferative disorders, the most common of which is KS.
- Four KS variants exist: classical, endemic/sub-Saharan African, epidemic (AIDS associated), and immunosuppression associated.
- In Central Africa, HHV-8–associated KS accounts for up to 25% of childhood malignancies.
- Endemic and epidemic KS in children characteristically is an aggressive lymphadenopathic disease with no cutaneous manifestations.
- Initiation of combination antiretroviral treatment (cART) in children with KS can be associated with immune reconstitution inflammatory syndrome and worsening signs and symptoms.
- Primary infection often is asymptomatic but can cause fever,

upper respiratory tract signs, and a nonspecific maculopapular rash.

- HHV-8 can cause primary effusion lymphoma, multicentric Castleman disease, and KSHV cytokine inflammatory syndrome associated with HIV infection.

Diagnosis

- Most diagnoses are based on combination of serologic tests for both latent and lytic antigens, combined with histologic examination of tissue specimens.

Management

- Most primary infections are self-limited and do not require specific treatment.

- No antiviral medications are currently licensed for the treatment of HHV-8 infections.

- cART of HIV infection decreases the risk for KS and is used as treatment for early-stage disease, with traditional chemotherapy added for more advanced KS.

DNA Viruses: Adenoviridae

OUTLINE

210 Adenoviruses

210

Adenoviruses

Upton D. Allen, Gail J. Demmler-Harrison

Adenoviruses are relatively small, nonenveloped double-stranded DNA viruses. They belong to the family Adenoviridae (from *adenos*, the Greek word meaning "gland") because they were first isolated from adenoid tissue. There are 51 human serotypes defined by biologic characteristics, including immunochemical methods, such as serum neutralization and hemagglutination.[1–5] However, the use of the term *type* has replaced *serotype*, given that the more recently identified types were determined using genomics and bioinformatics and not serotyping.[1,6] To date, there are 67 types that have been identified using different technologies. Types 1 to 51 were characterized by serotyping, whereas types 52 to 67 were determined by genomic and bioinformatics analyses. Typing and reclassification of adenoviruses remains in a state of flux. The types are classified according to their biochemical, structural, biologic, and immunologic characteristics into seven subgroups, A to G.[1–5] The current spectrum of adenovirus species and types in humans is shown in Table 210.1. Adenoviruses in subgroups B and C (notably C) have the ability to cause latent infections in lymphoid cells.

TABLE 210.1
Human Adenoviruses

Species	Types (Serotypes/Genotypes)
A	12, 18, 31, 61
B	3, 7, 11, 14, 16, 21, 34, 35, 50, 55, 66
C	1, 2, 5, 6, 57
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54, 56, 58–60, 63–67

Epidemiology

Transmission is mainly by direct spread from person to person through contact with infected respiratory tract secretions, fomites, and aerosols; enteric strains are transmitted by the fecal-oral route. Transmission also can occur through organ transplantation. Among transplant patients, reactivation of latent or persistent virus from the host can occur after the start of immunosuppressive therapy.[7,8] Reinfections with the same serotype can occur; these infections often are asymptomatic.[9]

Coinfections with more than one adenoviral type and with other respiratory viruses occur. Although not having the definite seasonality that is seen with other respiratory viruses, adenoviruses can produce sporadic outbreaks, most commonly during winter, spring, and early summer. No differences in incidence are apparent between males and females or among racial or ethnic groups. The incidence of infection appears greatest in lower socioeconomic groups and in situations of crowding. Epidemic disease commonly occurs in military recruits. Outbreaks, especially of pharyngoconjunctival fever, have followed exposure at swimming pools, summer camps, and childcare centers and in healthcare settings.

Adenoviruses can infect all age groups; however, the incidence peaks between the ages of 6 months and 5 years, and they are a leading cause of febrile illnesses in children. The use of molecular detection techniques has demonstrated a greater burden of adenoviral infections among childcare attendees than previously appreciated.[10] Tables 210.2 and 210.3 show the association between serotypes/types and clinical syndromes. The most common serotypes associated with respiratory tract disease are serotypes 1 through 7 and 21. Types 8, 19, and 37 are most commonly associated with epidemic keratoconjunctivitis, and serotypes 3, 7, 32, 40, and 41 have been associated with diarrhea. Disseminated adenovirus disease in immunocompromised children can be associated with several serotypes including 1 to 3, 5, 7, 11, 31, 34, 35, and 40 (see Table 210.2).[1,7,11,12]

TABLE 210.2

Clinical Illnesses and Associated Adenovirus Serotypes (Serotypes 1−51)

		Serotypes Involved[a]	
Syndrome	Signs and Symptoms	Frequently	Infrequently
Upper respiratory illness	Coryza, pharyngitis, fever, tonsillitis, with diarrhea	1–3, 5, 7	4, 6, 11, 14, 15, 18, 21, 29, 31
Lower respiratory illness	Bronchitis, laryngotracheobronchitis, bronchiolitis, pneumonia, fever, coryza, cough	3, 4, 7, 21	1, 2, 5, 8, 11, 14, 35
Pertussis-like cough illness	Paroxysmal cough, vomiting, fever, with upper respiratory tract symptoms	5	1–3, 12, 19
Infectious mononucleosis-like or Kawasaki-like illness	Fever, malaise, irritability, cervical lymphadenopathy, pharyngitis, rash, conjunctivitis	ND	ND
Acute conjunctivitis	Clear, watery discharge, chemosis, conjunctival injection, pruritus	1–4, 7	6, 9−11, 15−17, 19, 20, 22, 37
Acute hemorrhagic (follicular) conjunctivitis	Chemosis, subconjunctival hemorrhage, preauricular adenopathy, fever, sticky discharge	11	2–8, 14, 15, 19, 37
Pharyngoconjunctival fever	Pharyngitis, conjunctivitis, fever, coryza, headache, rash, adenopathy, with diarrhea	2, 3, 4, 7, 14	1, 5, 6, 8, 11−17, 19−21, 29, 37
Epidemic keratoconjunctivitis	Keratitis, headache, preauricular adenopathy, pharyngitis, diarrhea	3, 8, 19, 37	2, 4, 5, 7, 10, 11, 13−17, 21, 23, 29
Genitourinary tract disease	Cystitis (usually hemorrhagic), nephritis, orchitis, urethritis, cervicitis, ulcerative genital lesions, pharyngitis, fever	2, 37	1, 4, 5, 7, 9, 11, 18, 19, 31, 49
Gastrointestinal disease	Gastroenteritis with diarrhea and vomiting; abdominal pain with intussusception, pseudoappendicitis syndrome, or mesenteric lymphadenitis	3, 5, 7, 31, 40, 41	1, 2, 12–18, 21, 25, 26, 29, 31
Liver disease	Hepatitis	1–3, 5, 7	4, 31
Central nervous system disease	Meningitis, encephalitis, Reye syndrome	7	1−3, 5, 6, 11, 12, 26, 32
Cardiac disease	Myocarditis, pericarditis	7, 21	ND
Infection in immunocompromised hosts	Diarrhea, rash, upper respiratory tract illness, pneumonia, hepatitis, hemorrhagic enterocolitis, cystitis, disseminated disease	1, 2, 3, 5, 7,11, 34, 35	21, 29–31, 37–39, 43, 45
Fetus and newborn	Hydrops fetalis, myocarditis, pneumonia, hepatitis, disseminated disease	3	35

[a] Novel candidate types are being identified that are associated with disease (see Table 210.3).

ND, not determined.

Modified from Robinson C, Echarvarria M. Adenoviruses. In: Balows A (ed). Manual of Clinical Microbiology, 6th ed. Washington, DC, American Society for Microbiology, 1994, pp. 947–955.

TABLE 210.3

Clinical Illnesses and Associated Adenovirus Types (Types 52−67)

Types[a]	Disease States	References
52	Gastroenteritis	25
53	Keratoconjunctivitis	26–29
54	Keratoconjunctivitis	30–33
55	Acute respiratory distress syndrome	34, 35
56	Keratoconjunctivitis, neonatal pneumonia, urethritis	36–38
57	Conjunctivitis	39, 40
58	Gastroenteritis	41–43
59	Conjunctivitis	44
60	Conjunctivitis/keratitis (experimental)	45, 46
61	Gastroenteritis, hepatitis (proposed to be previously serotype 31)	47, 48
62	Gastroenteritis	49
63	TBD	50–52
64	Keratoconjunctivitis	53
65	Gastroenteritis	54, 55
66	Acute lower respiratory tract infections	56, 57
67	Gastroenteritis	58

[a] Data are emerging on the association between types 52−67 and disease states. In this regard, the documented associations with diseases are less than for the first 51 serotypes that were described. Some of the above types were previously designated as serotypes numbered less than 51.

TBD, to be determined.

Nosocomial adenovirus infections can spread rapidly to cause serious morbidity and substantial mortality, especially in neonatal intensive care or hematopoietic stem cell transplantation (HSCT) units.[13–20] Nosocomial adenovirus infections can be spread by contaminated hands of healthcare workers,[15] infected ophthalmologic specula, retractors and solutions,[13] and equipment such as pneumotonometers,[18,21] endotracheal tubes, and suction catheters.[15] Alcohol, detergents, and chlorhexidine do not eradicate adenovirus from hands or equipment because adenoviruses are nonenveloped viruses and therefore are resistant to these agents. Instruments contaminated with adenoviruses can be disinfected by immersion in a 1% solution of sodium hypochlorite for 10 minutes[22] or by steam autoclaving.[23] Adenoviruses can persist on hands despite handwashing for 10 seconds; therefore, disposable gloves that are changed between contacts with patients should be used to help control institutional outbreaks.[18,21] The use of gowns and masks is recommended for tracheostomy care.[16] Other measures to control adenovirus nosocomial infections are isolation and cohorting of ill patients.[13,14,18] Healthcare workers with epidemic keratoconjunctivitis should not have direct contact with patients until 14 days after the onset of disease in the second eye.[18] The incubation period usually is 2 to 14 days for adenovirus respiratory tract infection and 3 to 10 days for gastrointestinal infection.[23]

Clinical Disease

Adenoviruses cause a variety of syndromes (see Table 210.2),[24] which can be influenced by age, immune status, and site of infection. Syndromes associated with the newer types (52–67)[25–58] are less well defined than those associated with serotypes 1 to 51. Many endemic adenoviruses, such as subgenus C, types 1, 2, 5, and 6, can cause infection throughout the year and are associated commonly with prolonged but asymptomatic fecal excretion of virus. Other adenoviruses are associated with epidemic disease, common environmental exposure, or novel virus types to which most hosts are susceptible. Among asymptomatic individuals, virus can be present in peripheral blood lymphocytes, lung tissue, and normal duodenal epithelium.[59–62]

Respiratory Tract Infections

Adenoviruses cause 2% to 5% of respiratory tract infections, including rhinitis, otitis media, pharyngitis, exudative tonsillitis, cervical adenopathy, bronchitis, laryngotracheobronchitis, pertussis-like syndrome, bronchiolitis, pneumonia, pleural effusions, and hyperlucent lung syndrome.[63]

Tonsillitis is a common manifestation of adenoviral infections. This tends to occur in younger children (<3 years of age) compared with group A streptococcal tonsillitis, which occurs in an older age group (5–17 years of age).[64,65]

Adenoviruses account for approximately 10% to 20% of childhood pneumonias.[66,67] The most severe respiratory tract infections are due to adenovirus types 3 and 7, serotypes that also can cause necrotizing diseases.[15,68–70] Adenovirus genome type 7h has been associated with fatalities among children with lower respiratory tract infection (LRI).[69,70] Fatality was originally reported among adults infected with serotype 14 in the United States[71,72] Fatal serotype 14 cases also have been reported from Europe, and the occurrence of this serotype (variant 14p1) has been documented in other regions.[73–75] Obliterative bronchiolitis can develop in children with severe respiratory compromise associated with adenovirus LRI.[76,77] This complication is most common in those who require intensive care, mechanical ventilation, oxygen supplementation, corticosteroid therapy, or β-agonist agents.[76] Hyperlucent lung syndrome, bronchiectasis, and bronchopulmonary dysplasia in premature infants also have been linked to prior adenovirus infections.[13,17] Pertussis and pertussis-like cough illness can be caused by adenovirus alone or associated with a mixed infection with *Bordetella pertussis*.[78]

Pharyngoconjunctival Fever and Keratoconjunctivitis

Adenoviral pharyngoconjunctival fever is the constellation of conjunctivitis, fever, pharyngitis, and cervical or preauricular lymphadenopathy. Eye involvement consists of acute follicular conjunctivitis; sequelae are rare.

Epidemic keratoconjunctivitis, caused mainly by types 3, 8, 19, and 37, is a severe eye disease that usually occurs in adults. Novel serotypes also have been causative.[5,6] Pharyngitis can be associated. The clinical course is characterized by slow progression from foreign body sensation and photophobia to impaired vision, edema of conjunctiva and eyelids, and subconjunctival hemorrhage.[18] Acute symptoms can last 4 to 6 weeks. Diffuse epithelial engorgement can progress to punctate epithelial lesions followed by subepithelial keratitis, which may persist. Preauricular lymphadenopathy often is present. Epidemic keratoconjunctivitis can progress to pseudomembranous conjunctivitis and eyelid erythema and edema mimicking periorbital bacterial cellulitis.[17,79]

Gastrointestinal Infections

Adenovirus types 40 and 41 of subgroup F[80–82] and serotypes 3, 5, 7, and 31[81] are associated most commonly with a gastroenteritis syndrome, especially in children younger than 2 years of age. Other serotypes, including serotypes 2 and 8, also have been implicated.[81] Enteric adenoviruses are second only to rotavirus as a cause of infantile diarrhea.[82–85] Illness with fever and dehydration associated with enteric adenovirus infection is comparable with group A rotavirus illness.[85–88] However, enteric adenovirus diarrhea usually has no seasonality, lasts longer than most other infectious diarrhea syndromes, and is associated with more vomiting than that caused by rotavirus infection.[86,89]

Adenoviruses also have been associated with mesenteric lymphadenitis, appendicitis, and intussusception. Fulminant hepatic necrosis can occur in patients with disseminated adenoviral disease and in immunosuppressed patients.

Genitourinary Infections

Genitourinary adenoviral infection can result in acute hemorrhagic cystitis in both healthy and immunocompromised patients. Infection has been associated with nephritis, orchitis, and hemolytic uremic syndrome. In bone marrow transplant recipients, adenovirus-associated hemorrhagic cystitis can be prolonged and is associated with substantial morbidity, including severe pain and the need for blood transfusions. If infection occurs during the first 100 days after transplantation, disseminated disease can develop and mortality may be high.[12,90,91] Coinfection with other DNA viruses such as the polyomavirus BK virus has been reported.[90]

Cardiac Infections

Adenoviruses have been detected in specimens of pericardial fluid and myocardial tissue from patients with subclinical or mild acute myocarditis and pericarditis associated with disseminated disease.[92–94] Intrauterine adenoviral myocarditis with cardiac failure rarely is a cause of nonimmune fetal hydrops.[95,96]

Neurologic Infections

Adenoviral neurologic disease, including aseptic meningitis, encephalitis, and transverse myelitis occurs rarely. Adenoviruses have been detected in cerebrospinal fluid by cell culture and by polymerase chain reaction (PCR) and in brain tissue by histopathology using immunohistochemical staining.[97,98] Central nervous system involvement can occur as part of severe, disseminated disease, especially in immunocompromised patients. Adenoviruses have been associated with febrile seizures.[99]

Other Illnesses

Uncomplicated adenovirus-associated upper respiratory tract illness can cause fever beyond a week and also can cause persistent fever without a focus.[100,101] Adenovirus also can cause an infectious mononucleosis (IM)-like syndrome as well as a Kawasaki disease (KD)-like syndrome.[102,103] Distinctive features in children with adenovirus infection in one study were <4 KD-like features, predominance of species B or E, and higher viral burden compared with children with KD and incidental adenovirus detection.[104]

Immunocompromised and Special Hosts

Adenoviruses are important pathogens in immunocompromised hosts, especially HSCT and solid-organ transplantation patients.[1,2,105–109] In HSCT patients, the rates of adenovirus infections are 4% to 18%, with reported fatality rates up to 75%.[110] Most infections occur before engraftment during the first months after transplantation. Fever, pneumonia, hepatitis, hemorrhagic cystitis, gastroenteritis, and colitis are the most common clinical presentations, and widespread virus dissemination can be fatal.[110–115] Risk factors for adenoviral infection and death in HSCT patients include graft-versus-host disease, total-body irradiation, type of marrow graft, pulmonary disease, isolation of the virus from more than one site, and type of immunosuppressive regimen.[109,112]

Adenovirus infections occur in 10% of liver transplant recipients, often causing hepatitis in the transplanted organ or disseminated disease, with an overall fatality rate of 53%.[1,115,116] Infection in lung transplant recipients can be severe, causing pneumonia, obliterative bronchiolitis, and disseminated disease.[117,118]

Adenovirus infections occur in approximately 10% of renal transplant recipients. Acute hemorrhagic cystitis, with hematuria, frequency, dysuria, and fever, and rarely with renal injury, can result.[119]

Children with malignancies and AIDS can be infected with a variety of adenovirus serotypes, and serious, even fatal disease, involving liver and lungs, has been reported.[120,121]

Adenovirus infections in the fetus and newborn are rare but often severe.[122–129] Fetal death can result from nonimmune hydrops.[58,59,86,87] In addition, infections contracted during the first month of life can be fatal. These infections can be acquired nosocomially during outbreaks in neonatal special care units, perinatally from the mother, or postnatally from family members or other close contacts.[13–15,126,127,129] Risk factors for perinatal adenovirus infection include premature labor, prolonged rupture of membranes, and maternal fever with upper respiratory tract illness at the time of delivery.[126] Neonatal illness usually manifests with lethargy, fever, and hepatosplenomegaly, with onset within 10 days of birth. After a brief period of apparent stabilization, virus disseminates and hepatitis, pneumonitis, disseminated intravascular coagulation, and death ensue.

Diagnosis

Optimal methods to detect adenovirus infection vary according to the disease being investigated. Conventional methods include electron microscopy to detect adenovirus particles in feces or respiratory tract secretions, histopathology with immunohistochemical staining of tissue, virus isolation by culture, direct antigen, and molecular methods of detection.[103,130,131]

Adenoviruses can be isolated in a variety of cell culture systems.[131] Isolation of adenovirus from the nasopharynx, throat, urine, and stool supports the diagnosis of acute infection, although isolation of virus from these sites can occur in the absence of disease. Isolation of virus from blood, pleural, pericardial, or cerebrospinal fluid or from tissue provides strong evidence of invasive or disseminated adenovirus disease. Adenovirus produces a characteristic rounded “cluster of grapes” cytopathic effect in cell culture, usually within 3 to 5 days of incubation; virus-specific immunofluorescence assays can be used for definitive identification. Identification of adenovirus serotype requires neutralization or hemagglutination-inhibition tests. Some serotypes of adenovirus, such as types 40 and 41, are fastidious, and culture is not a sensitive method for detection. Some serotypes can be excreted for prolonged periods, thereby making the association between diseases and virus detection challenging.

Adenovirus antigens can be detected in respiratory tract secretions by direct fluorescence assay using commercially available reagents, with results available within 24 hours.[103] Other rapid antigen detection methods include immunochromatography and latex agglutination, which are particularly useful for stool samples for which immunofluorescence cannot be performed. A commercially available rapid immunochromatographic test can detect most adenovirus serotypes, in a wide variety of specimens, including feces, nasopharyngeal and respiratory tract secretions, eye and conjunctival swabs, and urine. The test is simple to perform, and results are available in <30 minutes.[132] The test is sensitive and specific compared with reference standards such as virus culture and DNA detection by PCR. False-positive reactions can be caused by the local eye anesthetic oxybuprocaine.[133]

Molecular methods of detection are favored by many laboratories. These methods can detect or quantify adenovirus DNA in respiratory tract secretions, feces, blood, and urine. Gene amplification techniques, such as PCR, are sensitive and can detect any adenovirus or specific adenovirus serotypes using unique genomic regions of primers, probes, or both.[134–136] In addition, serial quantitative PCR assays can be used to monitor transplant recipients prospectively.[137] If high or rising viral DNA levels are detected by serial quantitative PCR assays, intervention with antiviral and immunomodulating therapies and adjustment of immunosuppression regimens may be indicated to prevent serious or fatal disease.[138] Assays that amplify and detect partial or unique regions of the hexon genomic region have also been used to study the molecular epidemiology of adenoviruses.[44,139] Other test modalities (e.g., DNA microarray technology) are the subject of current research.[140–142]

Serologic methods can detect significant rises in antibody levels between serum collected during acute illness and convalescence 2 to 4 weeks later. Serologic methods include testing for group-reactive antibody (complement fixation test, enzyme immunoassay) or type-specific antibody (neutralization or hemagglutination-inhibition assay). Serologic diagnosis is not recommended because sensitivity may be ≤50% in acute infections in normal hosts and possibly lower in immunocompromised hosts.

Treatment and Prevention

Treatment of adenoviral diseases is primarily supportive. Most adenovirus infections in otherwise healthy people are self-limited and do not require treatment. Symptomatic infection of immunocompromised hosts should be treated with antiviral agents and reduction of immunosuppressants, if feasible. No consensus exists regarding the optimal management of symptom-free patients with detectable adenovirus viremia.

Trifluridine, ribavirin, and cidofovir are active against adenoviruses in vitro.[143–145] There are only anecdotal case reports and uncontrolled case series of treatment of serious adenovirus disease. Ribavirin has been administered with variable success, depending on the location and extent of the infection and immune function of the host.[11,144–146] Cidofovir has emerged as the preferred antiviral agent for treatment of adenoviral disease. Cidofovir at a dosage of 5 mg/kg administered intravenously once weekly, or at a reduced dosage of 1 to 1.5 mg/kg administered intravenously 3 times weekly has demonstrated clinical and virologic benefit in some patients.[147–151] Brincidofovir (1-*O*-hexadecyloxypropyl-cidofovir [CMX001]) is a lipid conjugate of cidofovir that is orally bioavailable and has substantially less nephrotoxicity than the parent drug.[152–155] Ganciclovir has activity against adenoviruses; however, studies are needed to clarify its effectiveness and role in the management of adenoviral disease.[156–158] Foscarnet has no demonstrable activity against adenoviruses.[156]

Treatment of hypoxemia or respiratory failure may require oxygen supplementation, mechanical ventilation, inhaled nitric oxide, or extracorporeal membrane oxygenation.[159]

Intravenous immunoglobulin has been used to treat patients with acute myocarditis and immunodeficient patients with pneumonia and disseminated disease due to adenovirus.[160,161] Novel immunoadoptive therapies that transfer virus-specific T-lymphocyte immunity to hosts who lack specific adenovirus T-lymphocyte immunity are being explored as therapeutic options in HSCT patients.[107,162,163]

Active immunization against adenovirus is not available outside of the military setting, and passive immunization with immunoglobulin has not been shown to be effective for immunoprophylaxis or outbreak control. Careful hand hygiene by caregivers and optimal disinfection of instruments and objects in the environment remain primary tools for preventing the spread of adenovirus in home, group childcare, and healthcare settings.

Key Points

Adenoviruses

Virology

- Double-stranded, nonenveloped DNA viruses in the Adenoviridae family
- Recently described type, resulting in at least 67 serotypes belonging to 7 subgroups
- Ability to cause latent or persistent infections

Epidemiology

- Affects all age groups, but peaks between ages 6 months and 5 years
- Transmission mainly by direct person-to-person spread
- Transmitted by contact with infected respiratory secretions
- Enteric strains transmitted by fecal-oral route
- Transmission possible by transplanted organs
- No classic seasonality as seen with other respiratory viruses; sporadic outbreaks can occur in winter, spring, and early summer

Clinical Features

- Symptoms depend on age, immune status, and sites of infection.
- Relationship exists between serotypes and sites of infection.
- Severe disease can occur in the immunocompromised host.

Diagnosis

- Conventional methods of detection include electron microscopy, histopathology, immunohistochemistry, culture, and direct antigen detection.
- Molecular methods have improved detection rates.
- Serology lacks utility in clinical setting and is notably unreliable in immunocompromised hosts.

Treatment

- Infections in normal hosts often are self-limited.
- There is no consensus on treatment of asymptomatic patients with detectable viremia.
- Early treatment of disease in the immunocompromised host is desirable.
- Effectiveness of antiviral agents is limited; intravenous cidofovir has emerged as the preferred agent for the treatment of systemic disease; brincidofovir is the orally bioavailable lipid conjugate of cidofovir and is associated with less toxicity.

DNA Viruses: Adenoviridae

OUTLINE

211 Human Papillomaviruses
212 BK, JC, and Other Human Polyomaviruses

211

Human Papillomaviruses

Loris Y. Hwang, Anna-Barbara Moscicki

Papillomaviruses are species specific and widely distributed among mammals and nonmammalian animal species. Human papillomaviruses (HPVs) are strictly epitheliotropic and cause infections and cancer of the skin and mucous membranes. Clinical conditions include anogenital infections and cancers, oral infections and cancers, and recurrent respiratory papillomatosis.

The Virus and Pathogenesis

HPVs are nonenveloped, double-stranded DNA viruses with a small circular genome of approximately 8000 base pairs. HPV genes are classified by their expression, occurring either early or late in the virus replication cycle. The early gene *E6* disrupts the antioncogene *p53*. *E7* disrupts the E2F/pRb complex, leading to activation of E2F, an important cellular transcription factor.[1] Both events lead to abnormal cellular proliferation. *E6* and *E7* also activate telomerase to lengthen telomeres, leading to the prolonged life of epithelial cells and blockade of apoptosis. *E6* and *E7* transcription is regulated by *E2*. Interestingly, viral integration, which occurs in more than 80% of HPV-related cancers, results in *E2* loss and the enhanced transcription of *E6* and *E7*.

HPV infection begins with viral invasion of the epithelial basal cells, particularly in the setting of epithelial disruption due to minor abrasions or inflammation. In the basal and parabasal layers, only the early viral genes are expressed, and viral DNA is replicated in low copy numbers, which likely contributes to evasion of the host immune system. In the more differentiated upper layers of the epithelium, expression of the late genes, *L1* and *L2,* produces capsid antigens that allow the release of fully infectious viral particles with physiologic epithelial desquamation. Inflammatory signals are absent because initial HPV infection does not induce cell death.

Extensive study of HPV as a cause of invasive cervical cancer has formed the basis of our understanding of HPV pathogenesis. Cervical cancer originates in the cervical transformation zone, where the proximal single-layered columnar epithelium transitions to the distal stratified squamous epithelium. At this juncture, the physiologic process of squamous metaplasia transforms the columnar cells into squamous cells. Squamous metaplastic activity is thought to be triggered by pubertal hormonal changes and thus is most common during adolescence and young adulthood, when initial HPV infection also commonly occurs.[2–4] However, the time between initial HPV infection and the development of invasive cancer is several decades in most healthy women. Active viral replication results in the benign changes of mild basal cell proliferation and perinuclear halos. In the past, these changes were described using different nomenclature when evaluated by cytology and by histology. In 2012, terminology was revised so that both cytologic and histologic results are reported according to the Bethesda system.[5,6] Benign changes are referred to as atypical squamous cells of undetermined significance (ASC-US) and low-grade squamous intraepithelial lesion (LSIL) (equivalent to cervical intraepithelial neoplasia, grade 1 (CIN 1) (Table 211.1).[7] High-grade squamous intraepithelial lesion (HSIL) (equivalent to CIN 2, 3) is considered a potential precancerous lesion. The changes of aneuploidy, altered chromatin texture, and increased nuclear volume are thought to be related to *E6* and *E7* expression in the epithelial stem cells. These cells have lost the ability to differentiate and demonstrate mutagenic consequences, including damage of chromosomal integrity, recombination of diverse DNA, and viral integration. The final mechanisms leading to invasive cancer are unexplained.

TABLE 211.1

Bethesda Terminology for Cytology and Histology

SQUAMOUS CELL ABNORMALITIES
Atypical squamous cells of undetermined significance (ASC-US)[a]
Atypical squamous cells, cannot exclude HSIL (ASC-H)[b]
Low-grade squamous intraepithelial lesion (LSIL)[a]
High-grade squamous intraepithelial lesion (HSIL)[b]
GLANDULAR CELL ABNORMALITIES
Atypical glandular cells (AGC)[c]
Endocervical adenocarcinoma in situ (AIS)[c]
Adenocarcinoma[d]

[a] Repeat cytology in 12 months.

[b] Refer to a gynecology specialist for colposcopy.

[c] Refer to a gynecology specialist for colposcopy including endocervical sampling; consider endometrial sampling depending on clinical history.

[d] Refer to gynecology specialist.

Immunity

Cell-mediated immunity is critical for HPV control, as evidenced by the increased risk for HPV-related anogenital cancer in individuals with depressed cell-mediated immunity.[8] Likely both genetic and epigenetic factors influence the host immune response. The primary mechanism for HPV persistence is thought to be evasion of both innate and adaptive immune responses. The antibody response to natural HPV infections is relatively low in titer compared with other systemic viral infections and is not universally detected.[9] Antibodies associated with natural infection may not be protective because women with HPV-associated invasive cervical cancer are more likely to have antibodies than women without cancer. In contrast, antibody levels induced by HPV vaccines are 60 to 100 times higher than those elicited by natural infections.[10]

Epidemiology and Clinical Features

The more than 200 HPV types are catalogued into the genera alpha, beta, gamma, mu, and nu.[11] Alpha types are further divided according to their natural tropism for cutaneous or mucosal sites. The types associated with cutaneous warts include HPV types 1, 2, 3, and 10. Of the 40 mucosal alpha types found in the anogenital or oral tracts, several are termed *high risk* (types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73, 82) based on their association with cancers of these regions.[12] Notably, HPV-16 and HPV-18 are responsible for about 70% of cervical cancers. HPV-16 plays a greater role in other HPV-associated cancers, being associated with more than 90% of HPV-associated anal and head and neck cancers. HPV-18 is more commonly associated with adenocarcinoma of the cervix. High-risk types also are associated with 50% of vulvar, vaginal, and penile cancers, although this association is dependent on histologic type.

The more common low-risk anogenital types (types 6, 11, 40, 42, 43, 44, 54, 61, 72, 73, 83) cause benign or low-grade cervical cellular changes and anogenital warts. Anogenital warts are caused most commonly by HPV-6 and HPV-11. HPVs associated with cutaneous warts are likely transmitted through nonsexual skin-to-skin contact. Fomite reservoirs appear to be important, as evidenced by a higher risk for plantar warts in those who expose their bare feet in communal bathrooms and showers. Anogenital HPV transmission occurs predominantly through sexual contact. Perinatal transmission can occur at birth from an infected mother to her newborn. Although consequent clinical disease in infants is rare, HPV-6 and HPV-11 can cause juvenile-onset recurrent respiratory papillomatosis or anogenital warts.

Anogenital Tract Infections

Initial HPV infection in the female anogenital tract typically occurs within 3 years of sexual debut. Lifetime risk reaches 80% in sexually active individuals. In developed countries, women aged 15 to 25 years exhibit the highest prevalence rates of 25% to 40%. Prevalence rates decline to approximately 15% in women 30 years and older and plateau at 10% at about age 40 years. The strongest risk factors for infection are new sexual partners and lack of condom use in women of any age. Ninety percent of infections detected by DNA testing resolve spontaneously within 36 months.[13] Thus infection by high-risk HPVs is common in the female anogenital tract and by itself is not concerning. Most young women with HPV demonstrate either no detectable lesion by cytology or only LSIL. LSIL is a benign manifestation of HPV, and studies show that most CIN 1 lesions regress spontaneously.[13]

Recurrent infections with new HPV types as well as the same types are common in young women.[14] Whether recurrence of the same type represents repeated new infections or reactivation of latent infection remains controversial. However, the rare persistent infection with a high-risk type is the necessary step for progression to cervical cancer. HPV infection detected in an older woman likely represents a persistent infection acquired years earlier. Hence HPV DNA cotesting, along with cytology, is recommended for primary screening in women older than 30 years.[15]

HPV prevalence in the male anogenital tract is estimated at 50% but varies widely from 1% to 73% according to sampling techniques and the number of HPV types and genital areas tested.[16] In contrast to women, prevalence does not vary with age,[17] leading to the hypotheses that male infections are primarily superficial and transient without inducing a protective immune response. The finding that within 6 months most men clear the initial HPV type detected supports this hypothesis.[18] Antibody titers are lower in men than women at all ages despite the higher prevalence of DNA detection in men than women at all ages.[19] It is hypothesized that HPV persistence also is essential to the development of penile cancer; however, there are no natural history data because penile cancer is very rare. Information about anal infection has been derived predominantly from studies of men who have sex with men (MSM). Prevalence of anal infection is approximately 60% in HIV-negative persons and approaches 100% in HIV-positive persons.[20–22] Anal HPV also is common in women, including adolescents.[23] The cumulative 1-year incidence of anal HPV in women was 70% in one study.[24] Clearance of anal HPV is slightly faster than cervical HPV infection.[25] It is thought that anal HPV has a similar natural history to cervical infection because similar precancerous lesions (i.e., anal intraepithelial neoplasia [AIN], grades 2 and 3) can be detected. The few studies in healthy women find that about 4% of women have AIN.[26] The natural history of these lesions remains unknown, but it is assumed they have similar potential to progress as do cervical precancers.

Anogenital Cancers

Cervical cancer is the second most common female malignancy worldwide, following breast cancer. About 500,000 new cases of cervical cancer are diagnosed annually worldwide, with 12,900 new cases projected for the United States during 2015.[27] The age-adjusted incidence is 7.7 per 100,000 women. US rates have decreased significantly since the 1970s because of the availability of routine cervical screening and management of precancerous lesions, but little to no change has occurred since the early 2000s. Barriers to healthcare remain a contributing factor in these new cases.

The rates for cancers of the vulva, vagina, anus, and penis are considerably lower than the rates for cervical cancer. In the US, the projected number of newly diagnosed cases during 2015 is 5150 for vulvar cancer; 4070 for vaginal cancer; 7270 for anal cancer; and 1820 for penile cancer.[27] Age-adjusted incidence rates for anal cancer are 2 per 100,000 women and 1.5 per 100,000 men. Rates are increased in MSM (non−HIV infected) to 37 per 100,000.[28,29] HIV increases the risk for anal cancer in men and women. Risk factors for anal cancer in women also include a history of cancers of the cervix, vulva, or vagina, and CIN 3.[30–32]

Oral Infections and Cancers

The prevalence of oral HPV infection has been reported to be 4% to 10%[33]; however, sampling techniques likely are inadequate to detect HPV from the areas around the tonsils and base of the tongue. Most cases of oral cancers are associated with alcohol and tobacco use. However, about 25% of head and neck cancers are HPV associated.[34] HPV association is increased in cancers at the tonsils and base of the tongue, with estimates as high as 75%. It is estimated that 2370 HPV-associated oropharyngeal cancers will occur in 2015 in women and 9356 in men.[35]

HPV Infection in Immunocompromised

Individuals

Individuals who are HIV infected or otherwise immunocompromised experience increased HPV prevalence, persistence, and progression to cancer. In HIV-infected MSM, the incidence of anal cancer is approximately 78 per 100,000 person-years.[20–22,29] Prevalence of cervical HPV infection reaches 80% in HIV-infected women, who also experience increased rates of cervical, vulvar, and anal cancers.[36] Invasive cervical cancer is an AIDS-defining condition.

Anogenital Warts

Warts (condylomas) are the most common clinical manifestations of anogenital HPV. US physicians see more than 1 million individuals yearly for anogenital warts, and 6% of sexually active 18- to 59-year-olds report a history of diagnosis of anogenital warts.[37] Approximately 90% of warts are caused by infections with HPV-6 and HPV-11, which almost never are associated with invasive cancers.

Anogenital warts are found in the external genitalia, upper thighs, inguinal folds, vagina, uterine cervix, and periurethral, intraurethral, perianal, and intra-anal areas. Anogenital warts can be papular, cauliflower-shaped, keratotic, flat, or pedunculated. They can be single or multiple. Individuals with a history of receptive anal sex are at higher risk for intra-anal warts. Infants can acquire anogenital or respiratory warts through perinatal acquisition from an infected mother. Congenital infection is rare. Anogenital warts in children of any age can indicate sexual abuse, with a particularly higher association with abuse in those older than 3 years.

Cutaneous Warts

Cutaneous warts commonly are papular, cauliflower-shaped, and keratotic. Plantar and palmar warts typically are flat. Cutaneous warts can occur in the perineal skin, but these HPVs rarely infect mucosal surfaces. Skin warts are most prevalent in school-aged children and young adults. Malignant transformation of skin warts rarely occurs in immunocompetent individuals. In contrast, immunocompromised patients can experience extensive skin warts with the potential for malignant transformation.

Recurrent Respiratory Papillomatosis

Juvenile-onset recurrent respiratory papillomatosis (JORRP) is a rare but serious disease usually caused by HPV-6 or HPV-11 acquired at birth. Incidence is estimated at 1 to 4 cases per 100,000 births annually.[38] Risk factors for JORRP are first-order birth, young maternal age, and maternal condylomas at delivery. Most cases are diagnosed by 5 years of age. Although most cases are isolated to the larynx, mucosal papillomas can affect the nasopharynx, oropharynx, trachea, and esophagus. Infants can exhibit a hoarse or weak cry, stridor, feeding difficulties, and failure to thrive. Older children can manifest hoarseness, stridor, and dysphonia. Rare cases of bronchopulmonary involvement with malignant degeneration have been reported. Papillomas are not precancerous, but airway obstruction is a serious consequence. Diagnosis is by direct laryngoscopic visualization and histologic analysis. Management can require extensive surgical excisions and chemotherapy. Many patients experience frequent recurrences necessitating multiple surgeries.

Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis is a rare genetic disorder characterized by susceptibility to persistent and extensive cutaneous HPV warts, with malignant transformation in up to one half of cases.

Laboratory Screening and Diagnosis

Cutaneous and anogenital warts are diagnosed reliably by history and examination. However, if therapy is ineffective, biopsy may be warranted to verify the diagnosis.

The primary mode of screening for cervical precancers and cancers is by cytology (Papanicolaou smear or liquid-based cytology) and HPV testing. Sampling should include both ectocervical scrapings and brush sampling within the cervical os to ensure sampling of the squamocolumnar junction. Screening guidelines for the general population were updated in 2012 by an expert panel convened by the American Cancer Society (ACS), American Society for Colposcopy and Cervical Pathology (ASCCP), and American Society for Clinical Pathology, and attended by 25 organizations.[39,40] Routine cervical cytology is recommended to begin at 21 years of age, with immunocompromise as the only exception. Screening frequency for immunocompetent women aged 21 to 65 years is cytology every 3 years. HIV-infected or immunocompromised women of any age should have cytology screening twice during the first year after diagnosis of HIV and then at 12 months. If all 3 tests are normal, screening can occur every 3 years. Starting at age 30 years, cotesting (cytology, as well as HPV testing with negative results for antibody to high-risk types) at 5-year intervals can be used as another mode of screening. The US Food and Drug Administration (FDA) recently approved a single HPV test for primary screening, which can start at 25 years of age and be done at 3-year intervals.

Direct cervical visualization is warranted in patients with bleeding, dyspareunia, or other symptoms. Overt cancer can be visualized without the assistance of magnification.

Abnormal cytology can warrant further diagnostic verification by colposcopy and histology sampling. Colposcopy at 10× to 16× magnifications with application of 3% to 5% acetic acid enhances vascular and tissue abnormalities and guides the clinician to optimal biopsy sites.

Screening for anal precancers and cancers remains controversial. However, because HIV-infected persons have the highest incidence, many clinicians perform anal cytologic screening in this group.[41] Anal screening practices must be conducted by skilled clinicians and supported by appropriate referrals. Some advocate for screening in women with a history of cervical or vulvar cancer or CIN 3. At minimum, these women should have routine digital rectal examinations and screening for anal cancer symptoms. There are no screening recommendations for vulvar, vaginal, penile, or oropharyngeal cancers.

Management

Current treatment for cutaneous and anogenital warts is directed toward destruction or excision of visible lesions. Treatment of cutaneous warts usually is for cosmetic reasons because the risk for malignant transformation is low and immune-mediated regression of lesions over a period of months to a few years is expected. Noteworthy exceptions are warts that cause bleeding, pruritus, or pain, especially plantar and subungual warts. Warts typically require costly repeated treatments associated with significant discomfort and high failure rates.

Cutaneous warts are treated with provider-applied cryotherapy, electrocautery, laser therapy, surgical excision, or patient-applied combinations of acetic acid–salicylic acid. External anogenital warts are treated with cryotherapy, surgical excision, or application of caustic agents. The 2010 Centers for Disease Control and Prevention (CDC) guidelines for patient-applied and provider-administered treatment of external anogenital warts are summarized in Box 211.1[42]

Box 211.1

Recommended Therapy for Genital Warts

Patient Applied

Podofilox 0.5% solution or gel: apply with swab or finger to visible warts twice daily for 3 days, followed by 4 days without treatment. Repeat this cycle for up to 4 cycles, using a maximum of 0.5 mL per day.

Or

Imiquimod 5% cream: apply once daily 3 times per week (or 3.75% cream, apply once daily) for up to 16 weeks. Wash the treatment area with soap and water 6–10 hours after the application.

Or

Sinecatechins (Veregen ointment 15%): apply 3 times daily for up to 16 weeks.

Provider Administered

Cryotherapy with liquid nitrogen or cryoprobe: repeat every 1–2 weeks.

Or

Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80%–90%: apply small amounts to each wart weekly, followed by air-drying. Take care to avoid applying to normal skin.

Or

Surgical removal by scissor excision, shave excision, curettage, laser, or electrosurgery

Alternative

Intralesional interferon

Or

Photodynamic therapy

Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Morb Mortal Wkly Rep 2015;64(RR-3):84–93.

The 2012 ASCCP guidelines for the management of abnormal cervical cytology in females of all ages are found at www.asccp.org/asccp-guidelines.[43] Women 21 to 24 years of age with ASC-US or LSIL should be observed with repeat cytology every 12 months for 24 months because many cases self-resolve.[39,44] Women with persistent ASC-US or LSIL at 24 months of follow-up or HSIL at any visit should be referred for further evaluation by colposcopy. Immediate treatment using excisional therapy without histologic confirmation of HSIL is unwarranted in young women. In HIV-infected or immunocompromised women, referral to a gynecologist for colposcopy should be made if ASC-US is found at two consecutive visits, or if LSIL or HSIL is found at any time.

Currently, HPV DNA testing serves as a triage test for risk stratification of women 25 years and older who have a cytologic diagnosis of ASC-US. HPV testing in women younger than 25 years is not recommended. Adults with ASC-US and a positive high-risk HPV DNA test result require colposcopy. Those with ASC-US but a negative HPV result can resume routine screening. The current FDA-approved assays detect the presence of 1 or more of 13 to 14 of the high-risk HPVs.

Prevention

Genital HPV infection is decreased by sexual abstinence, monogamy, limiting the number of sexual partners, and choosing a partner who has had fewer sexual partners. Condom use reduces the risk for infection and hastens LSIL resolution.[45,46] Cesarean delivery to prevent perinatal transmission is not recommended.

Three HPV vaccines are licensed by the FDA. The recombinant 9-valent vaccine (9vHPV, Gardasil-9), containing the L1 virus−like particles (VLPs) of HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58, is licensed for females aged 9 to 26 years and males aged 9 to 15 years (2014).[47] The quadrivalent vaccine (4vHPV, Gardasil), containing the L1 VLPs of HPV types 6, 11, 16, and 18, is licensed for females (2006) and males (2009) aged 9 to 26 years.[48] The bivalent vaccine (2vHPV, Cervarix), containing the L1 VLPs of HPV-16 and HPV-18, is licensed for females (2009) aged 9 to 26 years. All vaccines demonstrate >90% efficacy in preventing cervical cancer precursor lesions caused by their respective HPV vaccine types, among females who have not already been infected with those types.[49–53,54,55] Additionally, the 9vHPV and 4vHPV are efficacious in preventing vaginal and vulvar precancer lesions and anogenital warts in males and females caused by the respective HPV vaccine types.[10,56] Studies of MSM suggest high vaccine efficacy in reducing anal precancer lesions. There is no evidence of protection against any HPV disease in patients already infected with the vaccine types before vaccination.

The target group for HPV vaccination is young adolescents who have not initiated sexual activity. The CDC Advisory Committee on Immunization Practices recommends either the 9vHPV, 4vHPV, or 2vHPV vaccines for routine universal vaccination of females aged 11 to 12 years, and either the 9vHPV or 4vHPV for males aged 11 to 12 years. Routine "catch-up" vaccination is advised for females aged 13 to 26 years, males ages 13 to 21 years, and MSM and immunocompromised patients through age 26 years (Box 211.2). Additionally, any male 21 to 26 years old may be vaccinated.

Immunization can begin as young as 9 years of age. Any of the 3 approved vaccine products is acceptable and considered adequate. As of 2017, only the 9-valent vaccine is being distributed in the U.S. Patients who initiate vaccine at ages 9 through 14 years (nonimmunocompromised) should receive 2 doses at 0 and 6–12 months. Patients who initiate vaccine at ages 15–26, as well as immunocompromised patients, should receive 3 doses at 0, 1–2, and 6 months. If the schedule has been interrupted, vaccination can be resumed without repeating any doses. The vaccine series can be started and completed with different products: 9vHPV, 4vHPV, or 2vHPV for females, and 9vHPV or 4vHPV for males. Several studies have demonstrated the public health impact of marked drops in genital wart diagnoses after vaccine introduction, with evidence of herd immunity.[57] Other potential benefits may include prevention of penile, anal, and oropharyngeal cancers. Clinicians should remain alert for future vaccine updates and evolving information on the long-term duration of immunity and any new dosing schedules.

Box 211.2

Recommendations for 9-Valent, 4-Valent, and 2-Valent Human Papillomavirus Vaccines[a]; Advisory Committee on Immunization Practices, Centers for Disease Control[47]

Nine-valent, 4-valent, or 2-valent vaccine for females; 9-valent or 4-valent vaccine for males

Routine vaccination of females and males 11–12 years of age

Vaccination series can be started as young as 9 years of age at discretion of provider and parent

Catch-up vaccination for females 13–26 years of age and males 13-21 years of age who have not been vaccinated previously

Catch-up vaccination for males who have sex with males and immunocompromised males 22–26 years of age

[a] All 3 vaccines are approved and acceptable. As of early 2017, only the 9-valent vaccine is being distributed in the US. Patients who initiate the vaccine at ages 9–14 years (not immunocompromised) should receive a series of 2 doses of any of the products. Patients who initiate the vaccine at ages 15–26 and immunocompromised patients should receive a series of 3 doses.

Data from Meites E, Kempe A, Markowitz LE. Use of a 2-dose schedule for human papillomavirus vaccination—updated recommendations of the advisory committee on immunization practices. MMWR Morb Mortal Wkly Rep 2016;65(49):1405–1408.

Key Points

Human Papillomaviruses

Microbiology

- Double-stranded DNA virus contains 8000 base pairs.
- HPV infects basal cells of the mucosal or cutaneous epithelium.
- Early genes *E6* and *E7* are considered oncogenes.
- Late genes *L1* and *L2* are responsible for capsid antigens, necessary for release of fully infectious viral particles through physiologic epithelial desquamation.
- Vaccines are based on L1 antigens.

Epidemiology

- Transmission is person to person, including perinatal.
- Anogenital infection is common within 3 to 5 years after onset of sexual activity.
- Clearance of infections is common, with 90% of patients demonstrating clearance within 3 years.
- Persistence is essential for cancer development.
- Mucosal α types are classified as high-risk based on association with cancers of the cervix, anogenital area, and head and neck area.

- Herpesvirus-16 and herpesvirus-18 are responsible for approximately 70% of cervical cancer cases.

Screening and Diagnosis

- Cutaneous and anogenital warts are diagnosed visually by experienced clinicians.

- Clinically significant cervical infections are diagnosed by cytology screening; 2012 American Cancer Society, American Society for Colposcopy and Cervical Pathology (ASCCP), and American Society for Clinical Pathology guidelines advise routine screening to begin at age 21 years for the general population.

- Sexually active women who are HIV infected or immunocompromised should begin screening regardless of age.

- Women with high-grade squamous intraepithelial lesion (HSIL) on cytology should be referred to a gynecology specialist for colposcopy and histology to confirm results.

- Women aged 21–24 years with atypical squamous cells of undetermined significance and low-grade squamous intraepithelial lesion on cytology should be observed for 2 years for possible self-resolution.

- There are no clinical guidelines for screening for anal human papillomavirus infection.

Treatment

- Cutaneous and anogenital warts are treated by several patient-applied or provider-applied treatment options, as stated in the 2015 Centers for Disease Control and Prevention guidelines.

- Women with HSIL on histology should be treated by a gynecology specialist according to 2012 ASCCP guidelines.

BK, JC, and Other Human Polyomaviruses

Suchitra Rao

Viruses

Polyomaviruses are a family of small, ubiquitous DNA viruses. The two most commonly known human polyomaviruses are BK virus and JC virus, which were first described in 1971.[1,2] Subsequently, 10 other human polyomaviruses have been identified: WU and KI polyomaviruses in 2007; Merkel cell polyomavirus in 2008; human polyomavirus 6, human polyomavirus 7, and trichodysplasia spinulosa virus in 2010; human polyomavirus 9 in 2011; MW and MX polyomaviruses in 2012; and St. Louis polyomavirus in 2013.[3–12]

Polyomaviruses are small (40 nm in diameter), nonenveloped viruses with a double-stranded DNA genome and an icosahedral capsid comprising three structural proteins: VP1, VP2, and VP3. The viral DNA is a supercoiled, circular, double-stranded DNA of approximately 5000 base pairs. The genome is organized into three regions (early, late, and regulatory); each of which has specific functions.[13,14]

The outcome of polyomavirus infection is species specific. The polyomaviruses are important in human disease for two main reasons. Although polyomavirus infection usually is asymptomatic, in some cases it can be associated with a specific pathology. Infection of human cells by the human-specific viruses generally is limited to epithelial cells, fibroblasts, lymphocytes, or cells derived from the central nervous system (CNS). For example, JC virus infection can lead to progressive multifocal leukoencephalopathy (PML), whereas BK virus infection can lead to polyomavirus-associated nephropathy. Furthermore, several polyomaviruses encode oncogenic proteins that can undergo transformation in cell cultures, have tumorigenic activity in animals, and might be associated with cancer in humans.[15]

Epidemiology

Seroprevalence rates for the human polyomaviruses in adults are 82% for BK virus, 39% for JC virus, 55% for KI polyomavirus, 69% for WU polyomavirus, 25% for Merkel cell polyomavirus strain 350, 42% for Merkel cell polyomavirus strain 339, and 70% for trichodysplasia spinulosa virus.[16,17] Age-specific prevalence studies indicate that BK virus seroconversion peaks during childhood and that JC virus seroprevalence increases steadily from childhood into late adulthood.[18,19]

Fecal-oral, oral, and respiratory routes of transmission have been suggested for different human polyomaviruses.[20] Studies of urban sewage samples suggest that JC and BK viruses might be acquired through fecally contaminated water, food, and fomites.[21,22] Salivary shedding suggests that BK virus might be transmitted orally, KI and WU polyomaviruses have been isolated from respiratory tract specimens of children and immunosuppressed adults, and Merkel cell polyomavirus DNA can be detected in respiratory tract specimens of symptomatic individuals.[3,4,23–27] Other routes implicated for transmission of some polyomaviruses include blood transfusion, placenta, semen, and organ transplantation.[28,29] Transmission occurs predominantly through close contact.[30]

BK Virus

BK virus was isolated from urine of a renal transplant recipient whose initials were BK.[4] BK virus is an important cause of significant morbidity in kidney transplant recipients, with a predilection to cause severe nephritis in the allograft, leading to loss of the graft in up to 80% of cases.[31,32] It is also associated with hemorrhagic cystitis in 25% to 50% of patients with hematopoietic stem cell transplants.[33–36]

Primary infection typically occurs in childhood and is usually asymptomatic or associated with mild upper respiratory symptoms.[37] Primary infection is followed by dissemination of the virus to sites where infection persists, predominantly the urinary tract.[38] BK viruria usually correlates with the degree of immunosuppression, but asymptomatic viruria has been described in healthy as well as immunocompromised patients.[39] After renal or bone marrow transplantation, immunosuppression can lead to reactivation of BK virus in host renal cells. Risk factors for reactivation include older age, BK virus seropositivity, and high pretransplantation anti-BK virus immunoglobulin G.[40]

Hematopoietic Stem Cell Transplant Recipients

Hemorrhagic cystitis usually is seen 2 weeks after transplantation, which is later than the hemorrhagic cystitis associated with cyclophosphamide.[36] Symptoms include dysuria, urinary frequency and urgency, suprapubic pain, and hematuria. There is little difference between allogenic and autologous transplant recipients with respect to viruria.[41] There is a higher incidence of hemorrhagic cystitis in allogenic transplant recipients with graft-versus-host disease, which is likely associated with immune reconstitution.[42] Diagnosis is made by detection of BK virus DNA in the urine but ideally should be confirmed with renal biopsy.[43]

BK virus nephritis has been reported infrequently in hematopoietic stem cell transplant recipients and patients with leukemia.[44–48] However, this complication is severe and can lead to permanent renal failure. Therefore, patients with unexplained deteriorating kidney function should be evaluated for BK virus infection by polymerase chain reaction analysis of urine and blood followed by renal biopsy for immunostaining. BK virus also can cause pneumonitis, hepatitis, retinitis, and meningoencephalitis in patients with cancer.[49]

Kidney Allograft Recipients

BK virus–associated nephropathy is seen most commonly in renal transplant recipients and includes hemorrhagic and nonhemorrhagic cystitis, asymptomatic hematuria, ureteral stenosis, and interstitial nephritis.[43] Reactivation of latent virus has been observed in 30% to 50% of renal transplant recipients within 3 months after transplantation.[50,51] Clinical presentation varies from asymptomatic to elevated serum creatinine, fever, or hematuria.[52,53] About 80% of renal transplant recipients have BK viruria, 5% to 10% of those develop BK virus–associated nephropathy, and 50% to 80% of patients who develop nephropathy go on to graft failure.[50,54–56]

The diagnosis of BK virus–associated nephropathy usually is made in patients with viruria and renal insufficiency.[43] The presence of decoy cells (virally infected epithelial cells with irregular shape and enlarged, abnormal nuclei) is suggestive of BK virus infection, but decoy cells also are present in JC virus and adenovirus infections.[57,58]

Quantitative measurement of BK viral load in the plasma has a negative predictive value of 100% but a positive predictive value of only 50%.[31] A plasma viral load of $>10^4$/copies per milliliter has both 93% sensitivity and specificity for positive tissue histology of BK virus nephropathy.[59] Renal biopsy is the most definitive test for diagnosis through visualization of intranuclear inclusions and cell detachment; however, false-negative results can occur in up to one third of biopsies owing to the focality of virus in renal tissue.[59,60]

Treatment

Treatment usually is supportive, with hyperhydration, forced diuresis, bladder irrigation, and transfusion as indicated.[61–63] If hematuria is severe with clots, cystoscopy with clot removal and cauterization of the source may be necessary. Cystectomy may be required if intractable bleeding occurs.[64,65]

First-line therapy for BK virus–associated disease is reduction of immunosuppression.[66,67] Recommendations for adjunctive antiviral therapy are not established because of the paucity of data and lack of randomized clinical trials. Treatment with low-dose cidofovir (0.25 to 1 mg/kg up to twice a week) without probenecid, and leflunomide or quinolones, in combination with immunosuppression reduction, has been used with some reported success.[68,69] However, there is some concern that these agents are ineffective in vivo and have the potential for adverse side effects.[70]

JC Virus

JC virus is the etiologic agent of PML. The infectious nature of the disease was described in 1964 with the finding of virions within intranuclear inclusion bodies of oligodendrocytes.[71] In 1971, JC virus was isolated from the brain tissue of and named after a patient with Hodgkin disease.[2] The disease rarely has been reported in transplant recipients or patients with hematologic malignancies.[72–76]

Progressive Multifocal Leukoencephalopathy

PML is a demyelinating disease preferentially affecting the white matter of the brain and is caused by the replication of JC virus in myelin sheath–producing oligodendrocytes. The clinical presentation of PML can include visual disturbances, alterations in behavior, cognitive decline, difficulty with coordination, and limb paresis. Lesions are adjacent to hemispheric cortical structures. PML is usually fatal.[77]

PML occurs more often in immunocompromised patients with HIV infection, after solid organ transplantation, or after allogenic hematopoietic stem cell transplantation. An increased incidence also has been reported in patients treated with natalizumab for multiple sclerosis and efalizumab for psoriasis.[78,79] Rituximab also has also been implicated in development of PML; however, most of these patients had other immunocompromising conditions.[80] Other neurologic disorders associated with JC virus infection include granule cell neuropathy, encephalopathy, and meningitis.[81]

Brain biopsy is considered the gold standard for diagnosis of PML, with a sensitivity of 64% to 96% and specificity of 100%.[43] Viral DNA also can be detected in cerebrospinal fluid, with a sensitivity of 72% to 92% and specificity of 92% to 100%.[76,82] Cerebrospinal fluid usually shows mild pleocytosis and slight elevation in protein.

Magnetic resonance imaging in patients with PML typically shows supratentorial white matter disease with confluent, bilateral, but asymmetric lesions.[83] However, findings can be unilateral, and there may only be a single lesion. The parietal lobe is most commonly involved, followed by the frontal lobe. Occasionally, there is grey matter involvement, with the thalamus and basal ganglia most commonly affected.

Treatment

There is no specific antiviral therapy for JC virus infection. In HIV-infected patients, the primary goal is to optimize antiretroviral therapy. If this can be achieved, 1-year survival rates increase from 10% to 50%.[84] For patients not infected with HIV, immunosuppressive therapy should be reduced.[43,85] Cidofovir has activity in vitro, but in vivo efficacy remains unknown.[86] Other agents such as mefloquine, interleukin-2, cytarabine, chlorpromazine, and serotonin 5-HT2A receptor blockers (e.g., ziprasidone, risperidone, olanzapine, and mirtazapine) have been used for individual patients, and trials for some of these agents are underway.[87,88]

WU and KI Polyomaviruses

WU and KI polyomaviruses were discovered in 2007 in respiratory tract specimens and were named after the institutions in which they were discovered: Washington University and Karolinska Institutet. The clinical presentation appears to be similar to other respiratory viruses, including fever, cough, and other upper and lower respiratory symptoms.[89–91] Studies in healthy blood donors detected serologic evidence of WU polyomavirus infection in 69% and KI polyomavirus in 55%.[16] However, their causative role in respiratory tract illness remains controversial, even in immunocompromised patients, owing to the high rate of codetection with other respiratory pathogens and the presence of WU in symptom-free individuals.[3,4,90,92–94]

Merkel Cell Virus

The oncogenic potential for polyomaviruses has been reported in natural and experimental infections but remains controversial, except for Merkel cell carcinoma.[95] Merkel cell polyomavirus was detected in 2008 in patients with Merkel cell carcinoma, a rare but aggressive form of skin cancer. The overall age-adjusted incidence is 0.2 to 0.4 per 100,000 person-years, but the incidence is increased in immunocompromised patients.[5,96–99] Merkel cell polyomavirus DNA has been detected in 59% to 100% of Merkel cell carcinomas, and patients with this tumor have very high antibody titers compared with the general population.[100–104] The mode of transmission and pathogenesis of the virus remains unknown. There are no data regarding specific antiviral therapy.

Trichodysplasia Spinulosa −Associated Polyomavirus

Trichodysplasia spinulosa is a rare skin disease characterized by development of papules and alopecia on the face and is observed exclusively in immunocompromised patients.[105–107] In 2010, the trichodysplasia spinulosa−associated polyomavirus was discovered and identified in a skin lesion from a child who developed trichodysplasia spinulosa after cardiac transplantation.[7,108] A second confirmed case was reported in a 7-year-old girl with leukemia.[108] The overall seroprevalence has been reported to be 70%, and the presence of the virus in clinically unaffected individuals suggests that the virus can cause subclinical or latent infection.[7,17]

DNA Viruses: Hepadnaviridae

OUTLINE

213 Hepatitis B and Hepatitis D Viruses

213

Hepatitis B and Hepatitis D Viruses

Melissa G. Collier, Sarah Schillie

Hepatitis B Virus

Description of the Pathogen

Hepatitis B virus (HBV), a member of the Hepadnaviridae family, is an enveloped virus that contains a circular partially double-stranded DNA genome that is 3.2 kb in length. The small genome consists of four overlapping reading frames.[1,2] Because the presence of HBV is necessary for infection with the hepatitis delta virus (HDV), both pathogens are discussed in this chapter.

HBV has been subclassified by serologic subtype and genotype. Nine serologic subtypes of HBV (*adrq*$^{+}$, *adrq*$^{-}$, *ayr*, *ayw1*, *ayw2*, *ayw3*, *ayw4*, *adw2*, *adw4*) initially were described on the basis of the serologic heterogeneity of HBsAg.[2] At least 9 HBV genotypes have been described, designated A through I, with a 10th genotype J isolated from a single individual. HBV serotypes and genotypes vary geographically. Infection or immunization to one genotype confers immunity to all genotypes.[3,4]

Pathogenesis

HBV-associated liver damage is not a direct cytopathic effect of the virus but rather the consequence of the host immune response to infection (e.g., cytotoxic T-lymphocyte–mediated lysis of infected hepatocytes).[5,6] Viral clearance and resolution of infection or development of chronic infection depends on the effectiveness and specificity of the initial cytotoxic T-lymphocyte response. For patients in whom acute HBV infection resolves, the response is vigorous, with cytokine-mediated control of virus replication and relative sparing of infected cells.[7] For patients in whom chronic infection develops, the initial T-lymphocyte response might be suboptimal and more narrowly focused, with enough cytokines produced to suppress some viral gene expression but insufficient to clear the virus. Persistent infection develops because of "immune tolerance."[8,9] HBV integrates into human DNA, potentially resulting in oncogene activation and carcinogenesis by insertional mutagenesis. Some studies suggest that regenerative hyperplasia resulting from chronic inflammation eventually might lead to carcinogenesis.[10]

Hepatitis B surface antigen (HBsAg) indicates either acute or chronic HBV infection. People with positive HBsAg are infectious and can transmit the virus to others. The immunoglobulin M (IgM) subclass of antibody to the hepatitis B core antigen (IgM anti-HBc) indicates acute infection, whereas total IgG anti-HBc is a nonspecific marker of infection that can indicate acute, chronic, or resolved acute infection. Antibody to HBsAg (anti-HBs) is a marker of immunity and is present after resolution of acute infection, after vaccination, or through passively acquired antibody (i.e., hepatitis B immune globulin [HBIG]). Hepatitis B e antigen (HBeAg) indicates ongoing virus replication and increased infectivity. Antibody to HBeAg (anti-HBe) can be found in both acute and chronic infection; its presence usually is accompanied by decreased viral load and decreased infectivity (Table 213.1). Hepatitis B DNA (HBV DNA) is a marker of virus replication. Higher viral loads correlate with greater infectivity.[3]

TABLE 213.1

Interpretation of Serologic Markers for Hepatitis B Virus Infection

Serologic Marker				Interpretation
HBsAg	Anti-HBs	IgM Anti-HBc	Total Anti-HBc	

–	–	–	–	Susceptible; never infected
+	–	–	–	Acute infection, early incubation; transient, up to 3 weeks after vaccination
+	–	+	+	Acute infection
–	–	+	+	Acute infection, resolving
–	+	–	+	Past infection, recovered and immune
+	–	–	+	Chronic infection
–	–	–	+	False-positive (i.e., susceptible) past infection, or "low-level" chronic infection
–	+	–	–	Immune from vaccination

HBsAg, hepatitis B surface antigen; anti-HBs, antibody to hepatitis B surface antigen; IgM anti-HBc, IgM antibody to hepatitis B core antigen; total anti-HBc, total antibody to hepatitis B core antigen.

Epidemiology

Worldwide, HBV infection is one of the leading causes of infectious disease–related morbidity and mortality. An estimated 2 billion people—one third of the world's population—have serologic evidence of past or present HBV infection, and more than 240 million people are infected chronically. Each year, an estimated 780,000 people die from HBV-related liver disease, including cirrhosis and hepatocellular carcinoma (HCC).[11] In the United States, HBV infects an estimated 700,000 to 1.4 million persons and results in approximately 1800 deaths annually.[12]

Transmission

The principal modes of HBV transmission are (1) percutaneous, (2) sexual, and (3) perinatal.[13] HBV is present in high titers in blood and exudates (e.g., skin lesions) of acutely and chronically infected people. Moderate viral titers are found in semen, vaginal secretions, and saliva. Other body fluids that do not contain blood or serous fluid, such as feces or urine, are not generally a source of HBV transmission. Although HBV is found in human milk, breastfeeding has not been shown to increase HBV transmission.[14,15] Transmission between household contacts, especially in developing countries, can occur through contact with skin lesions such as eczema or impetigo; sharing of potentially blood-contaminated objects such as toothbrushes and razor blades; and in rare instances, in association with human bites.[16–18] All people who are HBsAg positive are potentially infectious and can transmit the virus to others.

HBV is stable in the environment for at least 7 days and can be found in high titers on environmental surfaces, even in the absence of visible blood.[19] Inoculation can occur from contact with environmental surfaces or equipment contaminated with HBV. The virus is inactivated by household bleach solution.[20]

Percutaneous and permucosal transmission of HBV results from transfusion of unscreened blood, injection-drug use, occupational exposure (e.g., needlestick injuries), and other nosocomial exposures (e.g., unsafe injections, breach in aseptic technique). In the US, blood transfusion is no longer a significant mode of transmission because all donor blood is screened for HBV markers. However, blood transfusion remains an important source of infection in many developing countries. Globally, unsafe injection practices are thought to account for 32% of new HBV infections annually[21]; the burden of disease from other unsafe medical practices is unknown. Nosocomial transmission is not limited to developing countries; in the US and other developed countries, nosocomial transmission is associated with improper infection control and continues to occur despite longstanding infection control recommendations and guidelines.[22–25] Since the mid-2000s, nosocomial HBV outbreaks have involved reuse of fingerstick devices (meant for individual use) for multiple persons, during assisted blood glucose monitoring, and reuse of single-use vials or devices for multiple patients.[26]

Horizontal transmission (or intrafamilial or household transmission) refers to percutaneous transmission from infected family members within the household (most often mothers and older siblings to young children).[27–37] Although this mode of transmission is most important in countries of high HBV endemicity, its occurrence in the US has been well documented.[38–41]

Sexual transmission of HBV results from sexual contact (heterosexual or homosexual) with an infected person. Increased risk has been associated with ≥1 sexual partners in a 6-month period; history of another sexually transmitted infection; and sexual practices that facilitate HBV transmission, such as anal intercourse.[42] Among young men who have sex with men (MSM), the prevalence of past or chronic HBV infection was reported to be 21%.[42,43]

Perinatal HBV transmission occurs during delivery and is highly efficient. In utero transmission is relatively rare, accounting for <3%

of vertical infections.[44–48] Risk for perinatal transmission is related to the HBeAg status of the mother; presence of HBeAg indicates increased viral load and infectivity. The risk for perinatal transmission is 70% to 90% for infants born to mothers who are both HBsAg positive and HBeAg positive, and 5% to 20%, for infants born to mothers who are HBsAg positive but HBeAg negative.[3,49–57]

Risk Factors, Prevalence, and Incidence of Infection in the United States

Risk factors for acute HBV infection in the US, including children ≥12 years of age, include injection-drug use, high-risk sexual behaviors (e.g., multiple sex partners and MSM).[12] Acquisition of HBV infection from transfused blood is rare in the US.[58,59] Other characteristics found in HBV-infected adolescents are homelessness and having run away from home.[60,61]

Data from the National Health and Nutrition Examination Survey (1999–2008) indicate that the lifetime risk for HBV infection in the US population is approximately 5%; chronic HBV infection is present among 0.3% of the population, corresponding to about 700,000 chronically infected persons. The prevalence of past or current HBV infection was higher among non-Hispanic blacks and persons of “other” race than among non-Hispanic whites and Mexican Americans, and prevalence was significantly higher among foreign-born persons. The US prevalence of past or current HBV infection was 0.5% among those 13 to 17 years of age and 4% among persons 30 to 39 years of age.[62]

Since the mid-1990s, the incidence of acute HBV infection in the U.S. has declined significantly. National surveillance data indicate that the incidence decreased from 11.5 per 100,000 population in 1985 to 0.9 per 100,000 in 2012 (Fig. 213.1). Incidence is estimated to be about 6 times the reported number of cases after adjustment for underreporting of cases and asymptomatic infections. In 2008, an estimated 19,000 people were newly infected.[12]

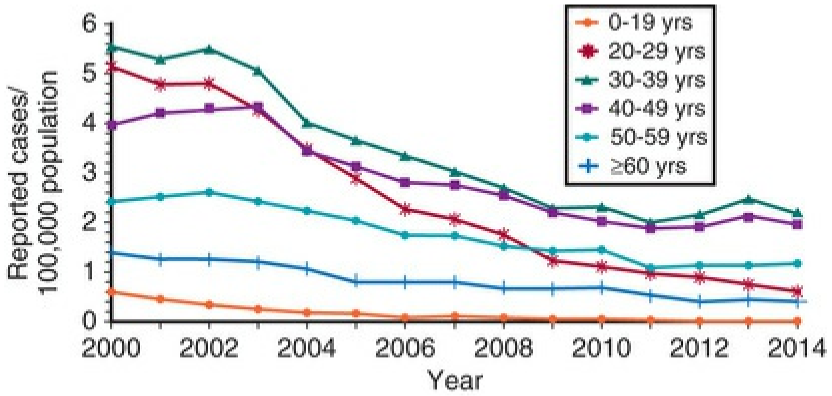

FIGURE 213.1 Reported incidence of acute hepatitis B in the United States, 2000–2014. (From the National Notifiable Diseases Surveillance System [NNDSS], Centers for Disease Control and Prevention. https://www.cdc.gov/hepatitis/statistics/2014surveillance/index.htm.)

The effect of hepatitis B vaccination is reflected in the dramatic decline in incident cases among the cohort of children for whom recommendations for routine infant and adolescent catch-up vaccination applied.[3] From 2000 through 2012, the incidence of acute HBV infection declined 95% (from 0.6 per 100,000 to 0.03 per 100,000) among children younger than 20 years.[12]

Global Prevalence of Infection and Patterns of Transmission

Countries and regions can be divided into areas of low (HBsAg prevalence <2%), intermediate (HBsAg prevalence of 2%–7%), and high (HBsAg prevalence of ≥8%) HBV endemicity based on the prevalence of chronic HBV infection in the general population.[3] Most high-endemic countries are in Africa and Asia. Western sub-Saharan African countries have some of the highest global age-specific HBsAg prevalence rates. East Asia has the highest prevalence of HBV infection among Asian regions. Global differences of HBsAg prevalence between males (3.9%) and females (3.5%) are small.[63]

Clinical Manifestations

Acute Infection

The usual incubation period for HBV infection is about 3 months but can vary from 6 weeks to 6 months. Clinical manifestations range from asymptomatic infection to fulminant hepatitis. The likelihood that symptoms will develop is age dependent. Perinatal HBV infections usually are subclinical, whereas symptomatic illness is noted in 5% to 15% of children 1 to 5 years of age and in 33% to 50% of older children, adolescents, and adults.[3,64]

Clinical signs and symptoms of acute HBV infection can include nausea, abdominal pain, vomiting, fever, jaundice, dark urine, changes in stool color, hepatomegaly, or splenomegaly. Malaise and anorexia might precede jaundice by 1 to 2 weeks. Fulminant hepatitis B is uncommon (<1%) but frequently leads to death or liver failure necessitating liver transplantation.[3]

Chronic Infection

Chronic infection is associated with progressive liver disease, including cirrhosis, liver failure, and HCC. Chronic infection is defined as persistence of HBsAg in serum for ≥6 months after acute infection.[3]

Most chronically infected people remain asymptomatic until development of cirrhosis or end-stage liver disease.[65] Cirrhosis can lead to the development of liver failure manifest by coagulopathy, ascites, encephalopathy, and increased risk for HCC. Among people with chronic infection, the overall annual incidence of cirrhosis is 2% to 3%.[66,67] At 5 years, the survival rate of people with compensated and uncompensated cirrhosis is 84% and 14%, respectively.[68] Risk factors for HBV-related cirrhosis and HCC include earlier age at infection, prolonged immune active phase of chronic infection, HBeAg positivity, and prolonged elevation of HBV DNA.[65,69] Although severe HBV-related liver disease is uncommon in childhood, chronic infection during infancy and childhood can lead to development of cirrhosis and HCC as early as the first decade of life.[70] Up to 25% of infants and older children with chronic infection eventually develop HBV-related cirrhosis or HCC.[3,71,72]

Extrahepatic Manifestations

Both acute and chronic HBV infection can be associated with extrahepatic clinical entities, including polyarteritis nodosa, membranous and membranoproliferative glomerulonephritis, polyradiculoneuritis, essential mixed cryoglobulinemia, porphyria cutanea tarda, polyneuritis, papular acrodermatitis, and thyroid dysfunction.[73–78] Urticarial rashes, arthralgia, and arthritis commonly are associated with acute HBV infection; thrombocytopenia preceding jaundice also has been reported.[79]

Natural History of Chronic Infection

There are four phases of chronic HBV infection: (1) immune tolerant, (2) immune active, (3) immune inactive, (4) and reactivation (or HBeAg-negative immune active).[68,80,81]

People in the *immune tolerant phase* are HBsAg positive and HBeAg positive and have high HBV DNA levels (>20,000 IU/mL), normal serum alanine aminotransferase (ALT) levels, and no to minimal hepatic inflammation or fibrosis.[68] Most chronically infected children will remain in the immune tolerant phase until late childhood or adolescence.[82]

The *immune active phase* is characterized by an active immune response resulting in inflammation (with or without fibrosis), hepatocyte damage and a resultant rise in serum ALT levels. Persons in the immune active phase are HBsAg positive, have HBV DNA levels >2000 IU/mL, and can be either HBeAg positive or HBeAg negative/anti-HBe positive.[68] People who remain in the immune active phase for prolonged periods are at high risk for developing cirrhosis and HCC.[69]

Persons in the *immune inactive phase* are HBsAg positive, have HBV DNA <2000 IU/mL, are HBeAg negative and anti-HBe positive, and have improvement of hepatic inflammation and fibrosis.[68] Risk for progression to HCC is lower among persons in the inactive phase than among persons in the active phase.[83]

Persons in the *reactivation phase* (or HBeAg-negative immune active phase) are HBsAg positive, HBeAg negative, and anti-HBe positive with HBV DNA levels >2000 IU/mL. There is active liver inflammation (with or without fibrosis), and serum ALT levels can be elevated or normal.[68] HBeAg-negative immune active disease often is caused by a mutant HBV, which can be more virulent than nonmutant forms.[84]

Chronically infected persons do not necessarily pass through the phases of chronic infection in a linear fashion. Chronically infected persons may spend little to no time in the immune tolerant phase. Twenty percent of HBeAg-negative persons will revert back to

HBeAg positivity[85]; 10% to 30% of HBeAg-negative/anti-HBe –positive persons will remain in the immune active phase with elevated serum ALT and HBV DNA levels; and 10% to 30% of HBeAg-negative/anti-HBe–positive persons will revert from the inactive phase to an anti-HBe–positive hepatitis with elevated serum ALT and HBV DNA levels.[86,87] As such, the current practice guidelines of the American Association for the Study of Liver Diseases recommend lifelong follow-up with repeated testing to monitor changes in the phase of chronic infection.[83]

Influence of Age and Hepatitis B e Antigen

Age at time of acute infection is the primary determinant of progression to chronic infection. More than 90% of perinatally infected infants develop chronic infection. Between 25% and 50% of children infected between 1 and 5 years of age become chronically infected, whereas only 6% to 10% of acutely infected older children and adults develop chronic infection.[3,64,88] Elderly adults have higher rates of developing chronic infection,[89,90]as do patients who have acute HBV infection while immunosuppressed or concurrently with an underlying chronic illness.[71]

Perinatally infected children usually remain in the immune tolerant phase for extended periods, whereas chronic infection acquired during later childhood or adolescence usually is accompanied by more active liver disease and elevated serum ALT values.[91] Children infected perinatally have lower annual rates of HBeAg loss than children infected later in childhood or in adolescence. Of Taiwanese children infected perinatally, HBeAg seroconversion occurred in <2% annually during the first 3 years of life and only in one third by 10 years of age.[92,93] Children infected horizontally clear HBeAg more rapidly; in one study, 35% of older Asian children cleared HBeAg >5 years after infection,[93] and 83% of European children cleared HBeAg during an average of 13 years of follow-up.[94]

Presence of HBeAg indicates ongoing virus replication. HBeAg-positive patients usually have high serum levels of HBV DNA. Clearance of HBeAg and development of anti-HBe (HBeAg seroconversion) are accompanied by reductions in serum HBV DNA and ALT levels and might be preceded by a temporary exacerbation of liver disease. HBeAg seroconversion occurs at a rate of 5% to 10% per year.[84] Most patients who seroconvert have little to no progression of liver disease (immune inactive phase). In these patients, the risk for HCC is reduced but remains higher than in patients without chronic infection.[95] Serologic reversion (reappearance of HBeAg) is common in the absence of anti-HBe. However, reversion to HBeAg positivity also can occur with loss of anti-HBe.[85]

HBeAg positivity during pregnancy greatly increases the risk for perinatal transmission. In the absence of appropriate postexposure prophylaxis, nearly all neonates born to mothers who are both HBsAg and HBeAg positive become infected, and 90% develop chronic infection. Clearance of HBeAg and development of anti-HBe is associated with decreased risk for perinatal transmission; approximately 25% of infants born to HBsAg-positive and anti-HBe−positive mothers become infected, and 10% to 15% develop chronic infection.[46,54] In a setting where infants generally receive postexposure prophylaxis, the relative risk for transmission for maternal HBeAg-positive status was an incidence rate ratio of nearly 80.[50]

Influence of Genotype

The clinical significance of HBV genotypes remains unclear. Existing studies suggest that genotype influences the time to HBeAg seroconversion and response to treatment. Among Alaska Natives, the median time to seroconversion is approximately 18 years among people with genotype C, 8 years among people with genotype F, and <6 years among people with genotypes A, B, and D. Reversion to HBeAg positivity is more common among Alaska Natives infected with genotypes C and F. Because genotype influences the rate of HBeAg seroconversion during childbearing years, genotype might play a role in the risk for perinatal transmission.[96,97]

An improved response to treatment with interferon α-2b (IFNα-2b) has been observed in adults with genotype A compared with adults with genotype D, and among adults with genotype B compared with genotype C.[98,99] Studies in children have shown mixed results. In one study, Chinese children with genotype B had an improved response to IFNα compared with children with genotype C.[100] In another study, Taiwanese children showed no difference in treatment response by genotype.[101]

Resolved Acute Infection and the “Recovery Phase” of Chronic Infection

Resolved acute infection is defined as the clearance of HBsAg, loss of detectable HBV DNA, and normalization of serum ALT levels; development of anti-HBs might occur. Resolved acute infection is not a risk factor for subsequent chronic liver disease or HCC.[102] However, viral clearance still might be incomplete; patients with a history of acute hepatitis B and apparent resolution (anti-HBs positivity and HBsAg negativity) can experience reactivation of hepatitis B if they become immunosuppressed,[103] and HBV DNA has been detected in blood of patients 20 years after resolution of acute infection.[104]

People with chronic infection who clear HBsAg enter what is often called the *recovery phase*. During childhood, the annual clearance rate of HBsAg is <1%.[83,105] People who clear HBsAg generally have a better prognosis, with improvements in hepatic inflammation and fibrosis over time.[106,107] However, HCC still can develop in HBsAg-negative people, and HBV DNA can be found in serum of a significant minority of HBsAg-negative people.[106,107] Practice guidelines recommend continued follow-up for previously chronically infected, HBsAg-negative people, to monitor for HCC.[108]

Laboratory Findings and Diagnostic Tests

Serum HBsAg and anti-HBs are the most useful screening tests for chronic HBV infection or immunity to HBV. HBsAg is present in most chronically infected persons. Lack of anti-HBs in an unvaccinated HBsAg-negative person indicates susceptibility to HBV infection.[3]

Routine screening for HBV infection is recommended for the following people: (1) all pregnant women; (2) all infants born to HBsAg-positive women after completing the vaccination series; (3) immigrants from regions of high or intermediate HBV endemicity (e.g., most areas of Asia, Africa, the Middle East, and Pacific Islands); (4) US-born people, who were not vaccinated as infants, whose parents were born in regions with HBsAg prevalence ≥8%;

(5) people with elevated serum ALT or aspartate transaminase levels of unknown etiology; (6) people with behavioral risks, including MSM and injection-drug users; (7) hemodialysis patients, (8) HIV-positive persons; (9) persons needing immunosuppressive therapy; (10) donors of blood, plasma, organs, tissues, or semen; (11) household, needle-sharing, or sexual contacts of persons known to be HBsAg positive; and (12) persons who are the source of blood or body fluids for exposures that might require postexposure prophylaxis.[65]

Screening for HBsAg is recommended at the first prenatal visit for all pregnant women.[3,109] Women in labor without HBsAg test information should have HBsAg serology on arrival. In addition, pretested women who have a history of certain risk factors (i.e., HBsAg-positive sexual partner or more than one sexual partner in the previous 6 months, evaluation or treatment for a sexually transmitted disease, injection-drug use, and clinical hepatitis) should be retested at the time of admission to the hospital for delivery.[3,110]

Serologic Diagnosis

Acute Infection.

After infection, the first serologic markers to become detectable are HBsAg and IgM anti-HBc, which appear within 1 to 2 months and are present when initial symptoms appear (Fig. 213.2). IgM anti-HBc is diagnostic of recent HBV infection. The presence of HBeAg, also detectable in acute infection, reflects viral replication and increased infectivity.[3,109]

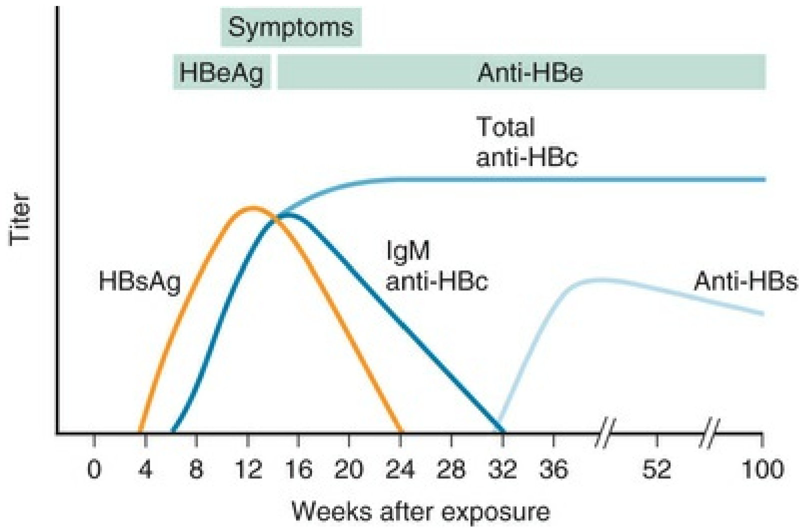

FIGURE 213.2 Serologic response to hepatitis B virus infection with recovery. Anti-HBc, antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; IgM anti-HBc, antibody of the immunoglobulin M subclass to hepatitis B core antigen.

Resolution of Acute Infection.

During resolution of acute infection, IgM anti-HBc is replaced by antibody of the IgG subclass (IgG anti-HBc), and anti-HBs develops (see Fig. 213.2). Anti-HBs is a protective, neutralizing antibody, and its presence indicates recovery from acute infection and immunity to reinfection. The period when all HBsAg has been neutralized by anti-HBs, and neither HBsAg nor anti-HBs is detectable, is referred to as the *window period*. During the window period, the only serologic marker of infection is IgM anti-HBc. During resolution, anti-HBe replaces HBeAg. In people with past HBV infection, IgG anti-HBc usually remains detectable for life, but anti-HBs might become undetectable in remote infection.[3,109]

Chronic Infection.

In chronic infection, HBsAg persists for >6 months, and anti-HBs does not develop (Fig. 213.3). People initially identified as HBsAg positive should be retested 6 months later to document clearance or chronic infection. Similar to acute infection with resolution, in chronic infection, IgM anti-HBc disappears and is replaced by IgG anti-HBc. HBeAg is variably present in chronic infection. When HBeAg is not present, anti-HBe usually is detectable.[3,109]

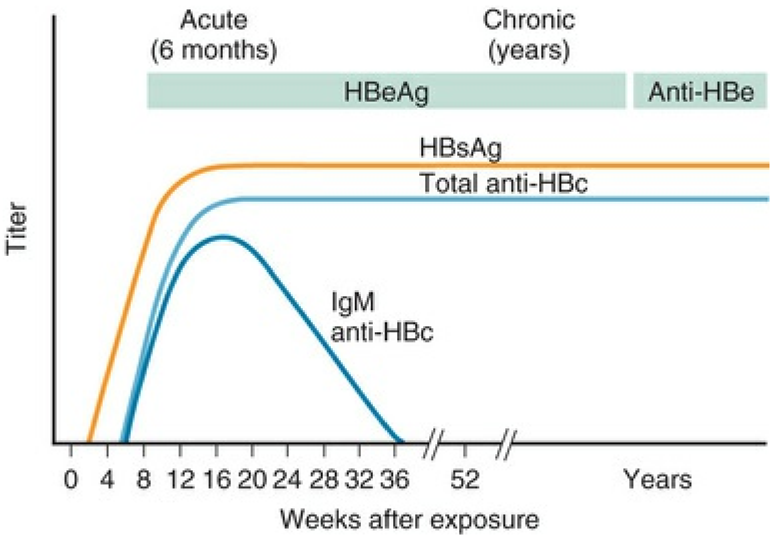

FIGURE 213.3 Serologic response to hepatitis B virus (HBV) infection with progression to chronic HBV. Anti-HBc, antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; IgM anti-HBc, antibody of the immunoglobulin M subclass to hepatitis B core antigen.

Perinatal Infection.

Maternal HBsAg generally does not cross the placenta; therefore, HBsAg found in serum of an infant shortly after birth usually indicates infection but can result from specimen contamination or can occur transiently after vaccination.[111] IgG anti-HBc and anti-HBs are transferred from mother to fetus through the placenta, and neither is a useful diagnostic marker of infection in infants. Passively acquired maternal anti-HBs and anti-HBc antibodies usually disappear within the first 1 to 2 years of life.[112,113]

Special Serologic Considerations.

Anti-HBs, with no other serologic marker of infection, is present after hepatitis B vaccination. HBsAg alone, with no other markers of infection, might be present very early in infection, before development of IgM anti-HBc, or immediately after hepatitis B vaccination (see Fig. 213.2). Transient HBsAg positivity from vaccine antigen, within the first 3 weeks after vaccination, has been documented in infants, adolescents, and adults.[114–116]

Anti-HBc without other markers of infection might be detected in three situations: (1) false-positive result; (2) remote, past infection with the loss of detectable anti-HBs levels; or (3) chronic infection in which the HBsAg level is below the level of detection for commercial assays. In the latter situation, person-to-person transmission is unlikely to occur.[3,117]

Assessment, Monitoring, and Referral

Although chronic HBV infection in childhood usually is asymptomatic, sequelae can become manifest in adolescence or adulthood. Chronically infected children are at increased risk for developing cirrhosis and HCC; as such, they require lifelong monitoring for disease progression.[3,84]

HBsAg-positive people should be retested 6 months later to determine whether they have developed chronic infection. Initial evaluation of chronically infected children includes laboratory testing for serum ALT, white blood cell (WBC) count, platelet count, HBeAg, anti-HBe, HBV DNA, and α-fetoprotein (AFP) level. Hepatitis B serology and serum ALT level are used to determine the phase of chronic infection. Decreased WBC and platelet counts can indicate liver fibrosis; AFP is a nonspecific marker for HCC. Family history of liver cancer and liver disease should be elicited and a baseline hepatic ultrasound performed.[84]

An expert panel commissioned by the Hepatitis B Foundation recommends that children in the immune tolerant and immune inactive phases of chronic infection have serum ALT and AFP levels tested every 6 to 12 months and HBeAg and anti-HBe tested annually. To determine whether children in the immune inactive phase have entered the reactivation phase, annual HBV DNA testing also may be useful. Children with elevated ALT, elevated AFP (≥10 ng/mL), or a family history of liver cancer or liver disease and children in the reactivation phase should be referred to a pediatric liver specialist for further evaluation.[84]

Treatment

No specific treatment is available for people with acute HBV infection. Neither HBIG nor corticosteroids are effective.[118,119]

An expert panel commissioned by the Hepatitis B Foundation recommends treatment for children with chronic infection based on serum ALT levels, age, liver biopsy findings, comorbidities, and family history of liver disease or liver cancer. Children with normal serum ALT levels should be monitored regularly. Persistently elevated serum ALT levels are defined as >1.5 times the laboratory upper limit of normal or >60 IU/mL, whichever is lower, on at least 2 occasions over 6 months in HBeAg-positive children or on at least 3 occasions over 12 months in HBeAg-negative children. Children with persistently elevated ALT levels are divided into 2 categories: children in the immune active phase and those in the reactivation phase. Treatment is indicated for children in the reactivation phase with persistently elevated serum ALT levels and moderate to severe hepatic inflammation or fibrosis. Benefit from treatment is unclear among children in the immune active phase with elevated serum ALT levels and minimal or mild hepatitis inflammation or fibrosis.[120]

Treatment response is not assessed until at least 6 months after completion of therapy. A response usually is defined as clearance of HBeAg. Other measurable markers of response are (1) development of anti-HBe, (2) clearance of HBsAg, (3) normalization of serum ALT levels, (4) reductions in serum levels of HBV DNA, and (5) improvement in histologic features of the liver.[105] The natural history of chronic HBV infection is an important consideration in the evaluation of results from clinical trials because spontaneous improvement occurs in many untreated patients.[121]

US Food and Drug Administration (FDA)-approved therapies for chronic hepatitis B are IFNα-2b, pegylated IFNα-2a (PEG-IFNα-2a), lamivudine, adefovir, entecavir, tenofovir, and telbivudine. The youngest age of approved use is 1 year for IFNα, 2 years for lamivudine, 12 years for adefovir, 2 years for entecavir, 12 years for tenofovir, and 16 years for telbivudine. PEG-IFN is not licensed for use in children with chronic HBV infection.[122]

Interferon-Based Therapies

Although few data are available for children treated with IFNα, some experts regard it as the drug of choice for patients aged 1 to 12 years with compensated liver disease. Available studies in Western countries report success (defined as HBeAg seroconversion) in 20% to 58% of treated children and 8% to 17% of untreated, control subjects.[123–126] In a large randomized controlled trial, chronically infected children with consistently elevated serum ALT levels treated with IFNα for 6 months were more likely than untreated controls to lose HBeAg (35% vs. 11%) and HBsAg (10% vs. 1%). No difference in treatment success was reported between children born in Asian or Western countries. For children who responded to treatment, serum ALT levels normalized and liver histologic features improved. Five of 70 treated children had virologic response (loss of HBV DNA and HBeAg) after completion of therapy; therefore it is not appropriate to declare treatment failure or to initiate another therapy until at least 6 to 12 months after treatment unless signs of decompensation are present.[126] A meta-analysis of 6 other studies concluded that children treated with IFNα had significantly increased clearance of HBV DNA and HBeAg compared with untreated controls.[127] In addition, other studies have shown that children younger than 5 years have improved response to treatment.[124,128]

Generally, IFNα is administered thrice weekly for 6 months for pediatric patients. Adverse effects of IFNα can be moderate to severe, including fever, headache, myalgia, neutropenia, worsening hepatitis, and depression or irritability, limiting a patient's ability to tolerate full doses or to complete a course of treatment. IFN therapy is contraindicated in patients with cirrhosis; therapy has been associated with exacerbation of hepatitis and hepatic decompensation.[120] Development of resistance has not been observed.

Antiviral Agents

Nucleoside and nucleotide analogues have emerged as alternative treatments for chronic hepatitis B. These agents have fewer adverse events than IFN-based therapies, although they induce resistant mutations.[84,120–141]

A randomized clinical trial indicated that chronically infected children with elevated serum ALT levels who received oral lamivudine once daily for 52 weeks were significantly more likely to have a virologic response compared with children receiving placebo (23% vs. 13%).[142] This response was maintained in 89% of participants at 24 months after discontinuing therapy. Patients from this study who did not respond to 1 year of treatment were continued for 24 additional months. Further clinical response was observed at 3 years, with an additional 21% achieving a virologic response. However, lamivudine resistance developed in 19%, 49%, and 64% of participants at 1, 2, and 3 years, respectively.[142,143] Children were followed for an additional 2 years (5 years total); 75% of controls maintained HBeAg seroconversion compared with 82% who received 1 year of treatment and 90% who received at least 2 years of treatment. Elevated serum ALT levels before treatment were associated with treatment success.[144] Lamivudine treatment was well tolerated.[142,143] Because lamivudine selects for mutations in the HBV polymerase (*YMDD* mutants), its usefulness as monotherapy may be limited. The optimal duration of therapy with lamivudine is unknown; children with HBeAg-positive chronic HBV infection should continue treatment for at least 6 months after seroconversion. The risk for virus-resistant mutants increases substantially over time; therefore discontinuation of lamivudine should be considered if there is incomplete viral suppression after 24 weeks of therapy, especially in the absence of advanced liver disease.[84,120,129,132,135]

In a randomized controlled study of adefovir, 173 HBeAg-positive children with elevated serum ALT levels were treated for 48 weeks. Children aged 12 to 17 years in the treatment group reached the treatment end point (HBV DNA <1000 copies/mL and normal serum ALT levels) more often than the untreated controls (23% versus 0%). Treated children aged 2 to 11 years did not have a significantly different outcome from untreated counterparts. No viral mutations were noted among any of the treated children, and treatment generally was well tolerated.[145]

Management of Patients With Chronic Hepatitis B Virus Infection and Their Contacts

Chronically infected patients should be counseled to limit alcohol consumption to avoid acceleration and progression of disease and should be immunized against hepatitis A.[146] Household, sexual, and needle-sharing contacts of chronically infected people should be identified. Unvaccinated contacts should be screened and receive the first dose of hepatitis B vaccine; contacts who are susceptible should complete the vaccination series. Sex partners of HBsAg-positive people should be counseled to use methods to protect themselves from sexual exposure until they are proved nonsusceptible.[3,109]

Special Considerations

There are special circumstances for which data from randomized controlled trials are unlikely to be available (e.g., pregnant adolescents, organ transplant recipients, and persons undergoing chemotherapy). These are cases for which individualized clinical judgment based on the best available information must be applied.[120,129]

Prevention

Hepatitis B vaccination has resulted in a significant decrease in incident hepatitis B cases in the US (see Fig. 213.1). Incidence has decreased most notably among children and adolescents since the 1991 Advisory Committee on Immunization Practices recommendation for universal infant hepatitis B vaccination, and later recommendations for vaccinating older unvaccinated children and adolescents.[12,147]

Vaccines and Schedules

Hepatitis B (HepB) vaccines are composed of HBsAg adsorbed to an adjuvant of aluminum hydroxide or aluminum hydroxyphosphate sulfate.[148,149] HBsAg elicits development of the neutralizing antibody, anti-HBs, which confers protection from infection. Plasma-derived vaccines were manufactured from HBsAg purified from the plasma of persons with chronic HBV infection. Recombinant vaccines have replaced plasma-derived vaccines and are produced through the insertion of the gene for HBsAg into yeast cells (*Saccharomyces cerevisiae*, or baker's yeast) and, less commonly, mammalian cells (Chinese hamster ovary cells). Recombinant vaccines are considered equivalent to plasma-derived vaccines in their immunogenicity and effectiveness. HepB vaccines are formulated to contain 5 to 40 μg of HBsAg protein per dose of vaccine and in the US do not contain the preservative thimerosal.[3,109,148,149]

In the US, DTaP-HepB-IPV is the only combination vaccine currently licensed for use in pediatric populations (infants and children through 10 years of age).[150–152] Combination vaccines should not be administered to infants younger than 6 weeks; monovalent HepB should be used for the birth dose.[3,109]

HepB typically is administered as a 3-dose series on a variety of vaccination schedules. In the US, the recommended schedule is administration of a first dose, followed by a second dose in 1 to 2 months, and a third dose 6 to 18 months after the first dose (i.e., 0, 1–2, and 6–18 months). For routine infant immunization, the first dose of vaccine should be administered at birth before hospital discharge, and the third dose should not be given before 6 months (24 weeks) of age. When DTaP-HepB-IPV is used to complete the series, a total of 4 doses of HepB are administered.[3,109] A 2-dose series for adolescents aged 11 to 15 years and a 4-dose series also are approved for use in the US.[3,109,153]

Prevention of Perinatal Hepatitis B Infection.

Infants born to HBsAg-positive women have a 90% risk for developing chronic infection if infected at birth. Infants not infected at birth remain at risk from transmission within the household. HepB combined with HBIG is highly effective in preventing perinatal and household HBV transmission when administered within 12 hours of birth and followed by completion of the vaccination series. Although HBIG should be administered if maternal HBsAg-positive status is learned through the infant's first week, every attempt should be made to administer HBIG within 12 hours of birth. HBIG should be administered in a separate site from the vaccine. HepB administered at birth, with or without HBIG, eliminates any theoretical risk for virus transmission through breastfeeding (Box 213.1).[3]

Box 213.1

Immunization Strategy to Eliminate Perinatal Hepatitis B Virus Transmission in the United States

Routine screening of all pregnant women for hepatitis B surface antigen (HBsAg), *plus*

Immunoprophylaxis of infants born to HBsAg-positive women and infants born to women with unknown HBsAg status

Universal routine vaccination of infants, beginning at birth

Infants born to HBsAg-positive pregnant women should receive postvaccination serologic testing (anti-HBs and HBsAg) at 1 to 2 months after completion of the vaccination series to determine their response to vaccination and their chronic HBV infection status. Infants who fail to respond to an initial HepB series, and are not infected, should be revaccinated with 3 additional doses and retested. Infants who develop chronic HBV infection should be referred for appropriate follow-up and care.[3]

A high HBV viral load (HBV DNA $\geq 10^8$ copies/mL) during pregnancy is associated with an increased risk for perinatal transmission despite appropriate infant postexposure prophylaxis. Some evidence suggests that antiviral treatment of these HBsAg-positive women during the third trimester of pregnancy might lower perinatal transmission risk.[50,154] However, no current recommendation exists for routine determination of viral load among HBsAg-positive pregnant women.[3,50]

Immunization of Infants With Birth Weight <2000 Grams.

Routine HepB immunization of preterm infants born to HBsAg-negative women weighing <2000 grams at birth should be delayed until the infant is 1 month of age or is discharged from the hospital, whichever is first; the 3-dose series should then be completed. If the infant's mother is HBsAg positive or her HBsAg status is unknown, the infant should receive HepB and HBIG within 12 hours of birth and complete 3 additional doses.[109] The birth dose does not count as part of the vaccine series for infants weighing <2000 grams.[3]

Vaccine Dosage and Administration.

The vaccine dosage varies by manufacturer and age of recipient. The typical dosage for infants, children, and adolescents ranges from 5 to 10 µg, and for adults from 10 to 20 µg.[3,109] A dosage of 40 µg is recommended for people with certain immunocompromising conditions such as those on hemodialysis.[109,155]

Vaccine Immunogenicity and Efficacy.

A seroprotective immune response to HepB is defined as development of anti-HBs ≥10 mIU/mL at 1 to 2 months after completion of the vaccine series. HepB is highly immunogenic, with seroconversion rates of ≥95% in healthy infants, children, and adolescents after completion of the 3-dose series.[156,157] Seroconversion rates vary, however, depending on the number of doses in the vaccine series, with much lower seroconversion after 1 dose compared with after series completion. Concurrent administration of HBIG does not reduce seroconversion rates. Lower rates of seroconversion are associated with prematurity, older ages (>40 years), and diabetes or other immunocompromising conditions.[158,159] In studies among infants and children infected with HIV, 20% to 78% attained seroprotective levels of anti-HBs after series completion.[160–165]

HepB starting at birth is 70% to 90% effective in preventing perinatal HBV infection, and HBIG administered within 12 hours of birth with completion of the vaccine series is 85% to 95% effective.[166,167]

Prevaccination and Postvaccination Testing.

Prevaccination testing for immunity is not indicated before routine vaccination of infants, children, and adolescents. However, children born in high- or intermediate-endemic countries should be tested before the first dose of vaccine is given.[65]

Because HepB is highly immunogenic, postvaccination serologic testing is not indicated after routine vaccination, except for the following groups: (1) infants born to HBsAg-positive mothers; (2) healthcare personnel; (3) persons with HIV and other immunosuppressive conditions, including those undergoing long-term hemodialysis; and (4) sex partners of HBsAg-positive people.[109,155,168] Postvaccination serology should be performed 1 to 2 months after administration of the last dose of vaccine. In people who do not respond to the primary series (i.e., anti-HBs concentration <10 mIU/mL), revaccination is recommended. Revaccination (usually 3 doses) is not associated with an increase in adverse events and substantially increases the rates of seroprotection in low responders or nonresponders. People who do not respond to a second series should be tested for HBsAg to determine whether they are chronically infected. Persons who are not chronically infected and do not respond to two vaccine series are unlikely to respond to further vaccination.[109,168]

Vaccine Safety.

The safety of HepB has been demonstrated in a large, prospective clinical trial[169] and in postlicensure safety analyses.[170] Pain at the injection site and increased temperature of >37.7°C are the most frequently reported adverse events.[169] The incidence of anaphylaxis to HepB is estimated to be 1 case per 1.1 million doses of vaccine distributed.[171] Several case reports of demyelinating or other neurologic diseases temporally associated with HepB have been reported, but no association has been observed in large, controlled studies.[172–175] Expert reviewers have found no supportive evidence for an association between HepB and neurologic disease.[176–178]

HepB is contraindicated for people with a history of hypersensitivity to yeast or to any vaccine component.[109] Pregnancy is not a contraindication to vaccination. Persons with a history of a serious adverse event (e.g., anaphylaxis) after receipt of HepB should not receive additional doses.[3,109]

Hepatitis B Immune Globulin and Postexposure Prophylaxis

HBIG is prepared from plasma containing high concentrations of anti-HBs. HBIG provides short-term protection (i.e., 3 to 6 months) from infection.[3,109,168] Currently, HBIG administered in conjunction with HepB is recommended for (1) infants born to HBsAg-positive mothers (or infants with birth weight of <2000 grams born to mothers with unknown HBsAg status)[3]; (2) unvaccinated sexual or needle-sharing contacts of an HBsAg-positive source person[109]; (3) unvaccinated persons with a percutaneous or mucosal exposure to HBsAg-positive blood or body fluids[109]; and (4) certain healthcare personnel after exposure to an HBsAg-positive (or unknown) source patient.[168] Administration of HBIG alone is the primary means of protection after exposure to HBV in known nonresponders to vaccination.[109,168] HBIG also is used in patients with HBV-related chronic liver disease who have undergone liver transplantation to reduce the incidence of recurrent HBV infection.[179]

Long-Term Protection

HepB provides long-term protection against HBV infection. Despite the loss of detectable levels of anti-HBs, immunocompetent persons who responded to vaccination remain protected, and a booster dose of vaccine is not recommended currently.[109,155,180–186] In most studies among infants and children who responded to the primary vaccine series, 40% to 85% had detectable levels of anti-HBs 10 to 22 years after vaccination.[187–199] Although breakthrough infections have been observed in a small proportion of children and adolescents as evidenced by development of anti-HBc, chronic infection (i.e., development of HBsAg) occurred rarely, and there were no reports of clinically apparent acute hepatitis B. Long-term studies among vaccinated adults have shown similar findings.[198,200,201]

Long-term protection from HepB is thought to be related to sensitization of B lymphocytes to HBsAg in the vaccine and development of an anamnestic antibody response on HBV challenge.[184,186] Booster dose studies have been used to simulate natural infection with HBV. In studies of children and adolescents who were vaccinated in infancy and childhood and who had a documented response to the primary vaccine series and lost detectable levels of anti-HBs, most (>90% in most studies) responded to a booster dose of vaccine 10 to 15 years after the initial vaccine series.[187–189,195,196] In people with immunosuppressive conditions, vaccine-induced protection might persist only as long as antibody levels remain ≥10 mIU/mL. In hemodialysis patients, anti-HBs levels should be tested annually and booster doses given when antibody levels are <10 mIU/mL; for other immunocompromised people (e.g., HIV-infected persons and hematopoietic stem cell transplant recipients), repeat testing may be considered.[109]

Hepatitis Delta Virus

Pathogenesis

HDV is an RNA virus that was first detected in hepatocytes of patients infected with HBV. HDV is a unique pathogen that can only infect cells and cause disease in the presence of HBV. As such, HDV is classified as a satellite virus or subviral agent because of its inability to encode its own envelope protein. HDV encodes a single protein, the hepatitis delta antigen (HDAg), which is encapsulated with HBsAg encoded by HBV (Fig. 213.4). Because of the unique requirement for HBV, infections with HDV occur in two forms: HBV-HDV coinfection and HDV superinfection. In HBV-HDV coinfection, HBV and HDV are transmitted simultaneously to a person who is susceptible to HBV infection. People who are immune to HBV infection, through either prior infection or vaccination, cannot be infected with HDV. In HDV superinfection, HDV is transmitted to a person with preexisting chronic HBV infection, which provides the HBsAg needed to establish the HDV infection.

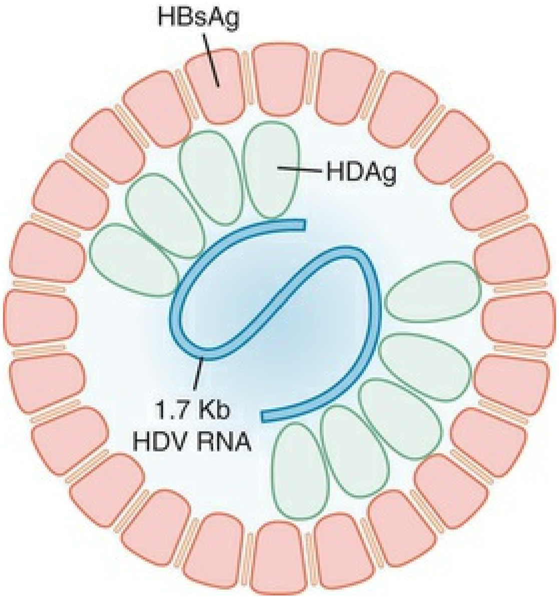

FIGURE 213.4 Schematic diagram of hepatitis D (delta) virus (HDV). HDAg, hepatitis D antigen; HBsAg, hepatitis B surface antigen.

Epidemiology

The epidemiology of HDV infection is similar to that of HBV infection. Percutaneous transmission of HDV is very efficient, as evidenced by the high prevalence of HDV among people who have frequent percutaneous exposures such as injection-drug users. An estimated 15 to 20 million people are infected with HDV worldwide, with areas of high endemicity in parts of the Mediterranean basin, the Middle East, Central Africa, and northern parts of South America.[202–204] In Western countries, prevalence of HDV infection can vary significantly among different populations of persons who inject drugs infected with HBV.[205,206] Hepatitis B vaccination can have a large effect on decreasing prevalence of HDV.[206] Although most HDV infections in low-endemic areas occur sporadically, outbreaks of HBV-HDV coinfection and HDV superinfection among injection-drug users and their sexual contacts have been described.[207] In high-endemic areas, transmission of HDV occurs primarily through person-to-person contact, especially in households, and usually results from HDV superinfection.

Clinical Manifestations

The incubation period for HBV-HDV coinfection ranges from 6 to 24 weeks. One feature that might distinguish HBV-HDV coinfection from other viral hepatitides is a biphasic course of illness, with two peaks of liver cell damage: the first is related to the appearance of HBV antigens in the liver, and the second to the appearance of HDV antigens. Approximately 2% of coinfected people become chronically infected.[208] In people HBV-HDV coinfection, fulminant hepatitis develops more often than in people with HBV monoinfection.[209]

The incubation period for HDV superinfection ranges from 2 to 8 weeks. Fulminant hepatitis occurs more often with HDV superinfection than with acute HBV infection alone.[210] In contrast to HBV-HDV coinfection, HDV superinfection results in chronic HDV infection in up to 90% of patients, and most patients progress to cirrhosis.[211,212]

Laboratory Findings and Diagnosis

HDV-infected people produce both IgM and IgG antibodies to the hepatitis delta antigen (anti-HDV). During acute HBV-HDV coinfection, antibodies are produced to both HBV and HDV antigens, but the anti-HDV response often is weak and might be delayed by several months. Because anti-HDV might not be present until several weeks after onset of illness, diagnosis of HDV infection might require testing of acute and convalescent sera; HDV infection also can be diagnosed using polymerase chain reaction assays.[213] Anti-HDV often does not persist, making diagnosis of past coinfection difficult. In contrast, HDV superinfection produces a brisk anti-HDV response that persists throughout chronic infection.[214] Acute HBV-HDV coinfection usually can be distinguished from HDV superinfection by the presence of IgM anti-HBc. The IgM anti-HDV response is not useful for distinguishing acute from chronic HDV infection because IgM anti-HDV production persists throughout chronic infection.[215]

Treatment

IFNα-2a is the only therapy approved by the FDA for chronic HDV infection. Data are limited on the effectiveness of IFNα in children. In a study using 3 to 5 MU/m^2 of IFNα, clearance of HDV viremia occurred in 2 (15%) of 13 children treated for 24 months; however, no significant improvement in liver histology was noted.[216]

Liver transplantation for end-stage chronic HDV infection has a 5-year survival rate as high as 88%. The success of liver transplantation for chronic HDV infection is attributed to the suppressive effect of HDV on HBV replication, which greatly reduces the posttransplantation HBV reinfection rate in the grafted liver. When HBIG is used for prophylaxis before liver transplantation for chronic HDV infection, the HBV-HDV reinfection rate is about 10%, compared with close to 100% HBV reinfection rate due to HBV alone.[217]

Prevention

Hepatitis B vaccine is the single most important tool to prevent HBV-HDV coinfection. Administration of HepB, and HBIG if indicated, at birth provides protection against HBV infection and HBV-HDV coinfection.[109] No vaccine exists to prevent HDV superinfection in HBV-infected persons; prevention depends on modification of behaviors, such as safer sexual and drug-injection practices.

DNA Viruses: Parvoviridae

OUTLINE

214 Human Parvoviruses

214

Human Parvoviruses

Kevin E. Brown

Parvoviruses, small (20 to 25 nm), nonenveloped, icosahedral, single-stranded DNA viruses with a linear genome of between 4500 and 5600 nucleotides, are common infectious agents of animals, including birds and insects, as well as humans.[1] At least five different genera of parvovirus have been detected in humans: bocaparvoviruses; dependoparvoviruses; erythroparvoviruses; protoparvoviruses; and tetraparvoviruses. Human bocavirus (HBoV)[2] has been identified in respiratory secretions of young children with acute wheezing and lower respiratory tract infections.[3] However, the contribution of HBoV as an etiologic pathogen for respiratory disease currently is unclear because HBoV often is found in the presence of other pathogens.[4,5] Dependoparvoviruses are nonpathogenic, and the role of the human partetraviruses (Parv4/5[6]) found in blood and the protoparvoviruses (Bufavirus,[7] Tusavirus[8]) is unclear. Parvovirus B19 (B19V), a member of the *Erythroparvovirus* genus, is the best characterized human parvovirus and is the cause of erythema infectiosum, transient aplastic crisis, pure red cell aplasia, and hydrops fetalis and is the focus of this chapter.

Microbiology and Pathogenesis

The single-stranded DNA genome encodes one major nonstructural protein,[9] which mediates cytotoxicity,[10] and two capsid proteins, VP1 and VP2, which self-assemble to form virus-like particles in vitro.[11] Based on the viral sequence, B19V can be divided into three distinct genotypes (genotypes 1, 2, and 3),[12] but all cause similar disease patterns, and there is serologic cross-reactivity—and thus a single serotype has been described.[13]

B19V is highly erythrotropic with efficient viral replication only occurring in late erythroid precursor cells. Virus-induced cytotoxicity therefore results in arrest of red cell production and reticulocytopenia. In patients who have increased erythropoiesis, such as those with sickle cell or hemolytic anemia, B19V infection may induce a transient aplastic crisis. In patients who are immunosuppressed and unable to mount an appropriate neutralizing antibody response, B19V infection can cause pure red cell aplasia and chronic anemia.

The erythroid specificity is in part due to the tissue distribution of the receptor for B19V, the blood group P antigen, also known as *globoside*.[14] This antigen is found in the erythrocyte precursors in bone marrow as well as in a variety of other tissues, including megakaryocytes, endothelial cells, placenta, fetal myocardium, and fetal liver. Rare individuals who lack blood group P antigen are naturally resistant to parvovirus B19 infection.[15] Some of the clinical consequences of B19V infection, including the rash, are immune mediated.

After infection there is a brisk viremia, which peaks at $>10^{12}$ virus particles (international units)/mL of blood (Fig. 214.1). Viremia often is accompanied by a nonspecific febrile illness. In immunocompetent individuals, an immunoglobulin M (IgM) and IgG antibody response is mounted, and the concentration of virus in blood drops. The second, immune-mediated phase of illness coincides with the antibody response (see Fig. 214.1). Typical manifestations of this phase of the illness are the rash of fifth disease, arthralgia, and arthritis. In normal immunocompetent hosts, infection resolves, although low levels of B19V DNA can be detected by polymerase chain reaction (PCR) in blood and tissues for months to years after acute infection.[16–18] Chronic, high-level viremia can occur in immunocompromised individuals, who do not make neutralizing antibody (see Fig. 214.1).[19]

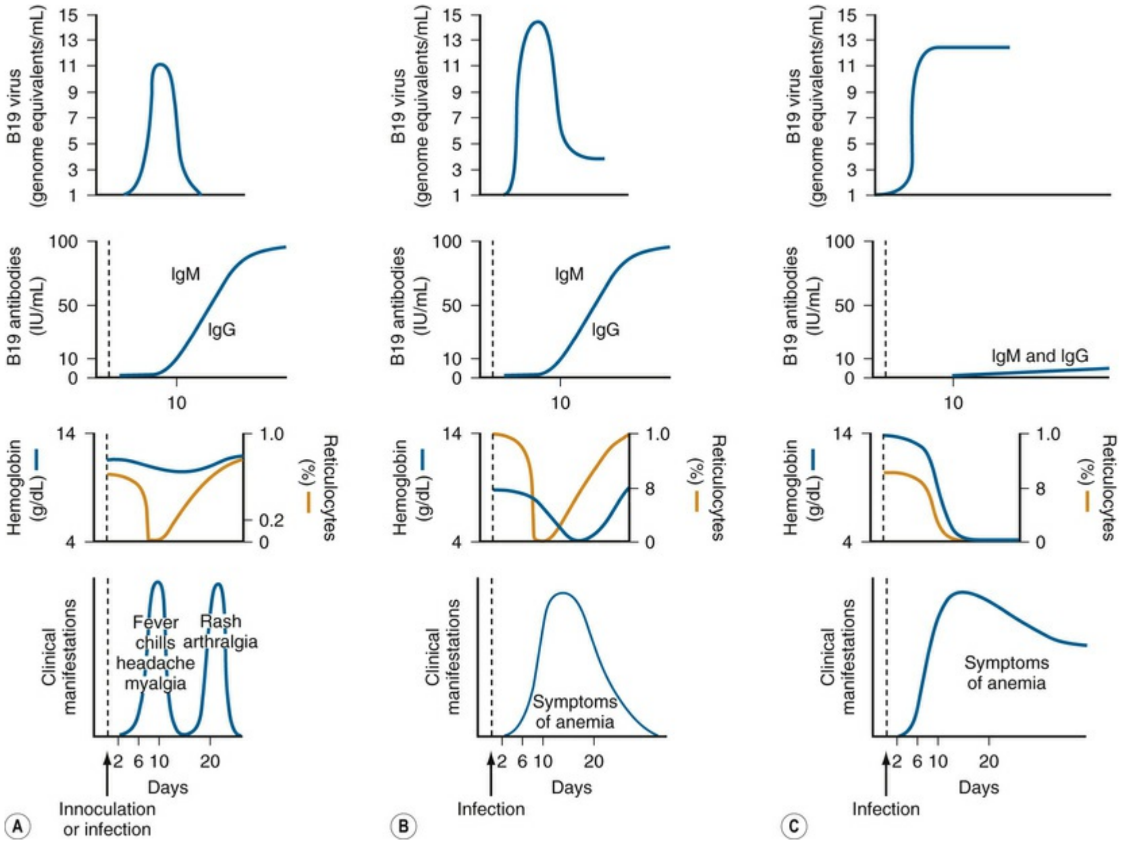

FIGURE 214.1 Schematic of the time course of parvovirus B19 infection, showing the associations of viremia, antibody production, and clinical symptoms in three groups of individuals: (A) fifth disease; (B) transient aplastic crisis; and (C) chronic bone marrow failure. IgG, immunoglobulin G; IgM, immunoglobulin M. (Redrawn from Young NS, Brown KE. Parvovirus B19. N Engl J Med 2004;350:586–597.)

Epidemiology

Key Points

Parvovirus B19

Epidemiology

- Parvovirus B19 (B19V) infection is common worldwide
- In temperate climates, most infections occur in the spring, with epidemics occurring every several years
- Approximately 50% of persons aged ≥15 years have evidence of

past infection

- Transmission is predominantly through the respiratory route, although transmission through blood and blood products can occur

Pathogenesis

- B19V replication occurs in late erythroid progenitor cells in bone marrow, leading to cessation of red cell production

Clinical Features

- Depend on host immune and hematopoietic status

Treatment and Prevention

- No specific antiviral treatment

- B19V vaccine in development

Parvovirus B19 infection is a common illness of childhood; by 15 years of age, approximately 50% of children have detectable IgG antibody.[20,21]

In temperate climates, most infections occur in the spring, with mini-epidemics occurring at regular intervals several years apart.[22,23] The highest risks for transmission are between close contact within households and schools,[24] and secondary infection rates approach 50% in households.[25] Transmission is predominantly through the respiratory route, probably by droplet spread, and is highest at the time of viremia, before the onset of rash or arthralgia.

Persons who have hemolytic anemias or decreased red cell production are at increased risk for severe anemia or transient aplastic crisis when infected with B19V. Globally, many children have severe anemia due to malaria, chronic parasitic infections (e.g., hookworm), and nutritional deficiencies (e.g., iron, vitamin A, vitamin B_{12}). Studies investigating the relationship between parvovirus B19 and these conditions indicate that B19V infection may be an important contributor to severe anemia, especially in malaria endemic regions.[26–31]

B19V infections also can occur as a result of transfusion of blood or blood products.[32] Most reported cases of transfusion-related infection are due to pooled components, especially factor VIII and IX concentrate, rather than individual units. B19V is resistant to both heat and solvent-detergent inactivation.[33] In July 2009, the US Food and Drug Administration issued a guidance for nucleic acid testing of blood to reduce the risk for transmission of B19V by plasma-derived products. Other countries have similar policies.[34]

Clinical Manifestations

Most infections caused by B19V are asymptomatic or mild. When infection is associated with symptoms, a variety of disease manifestations, depending on the immune status of the host, can be observed (Table 214.1).

TABLE 214.1

Diseases Associated With Human Parvovirus B19 Infection

Disease	Acute or Chronic	Host(s)
Fifth disease (erythema infectiosum)	Acute	Normal children
Polyarthropathy syndrome	Acute	Normal adults
Transient aplastic crisis	Acute	Patients with increased erythropoiesis
Persistent anemia	Chronic	Immunodeficient or immunocompromised patients
Hydrops fetalis or congenital anemia	Chronic	Fetus (<20 weeks)

Erythema Infectiosum

Key Points

Erythema Infectiosum (Fifth Disease)

Epidemiology

- Common presentation in childhood

Clinical Features

- Initially, a nonspecific febrile illness

- Classical slapped cheek appearance only seen in children
- Followed by lacy rash over rest of body
- Joint pain or arthritis can accompany rash

Diagnosis

- Difficult to distinguish from other childhood exanthems
- Laboratory diagnosis by detection of parvovirus B19–specific immunoglobulin M antibody

Treatment

- Symptomatic treatment only

The most common manifestation of B19V infection is erythema infectiosum (also known as *fifth disease,* or *slapped cheek disease*), a mild febrile illness with rash.[35] Studies in adult volunteers demonstrated a minor febrile illness that began about 8 days after nasal inoculation of virus and was associated with mild hematologic abnormalities during the second week and facial rash at 17 to 18 days (see Fig. 214.1A).[36]

After the appearance of the classical "slapped cheek" rash (Fig. 214.2), the rash can spread to the trunk and limbs, often in a lacy reticular pattern (see Fig. 214.2B). The rash can be exacerbated by exercise, emotion, hot baths, or sunlight. The intensity and distribution of the rash varies. Among adults, the slapped cheek rash may not be apparent. The rash can be difficult to appreciate in dark-skinned individuals, or to distinguish from other viral exanthems, such as rubella (see Fig. 214.2D).

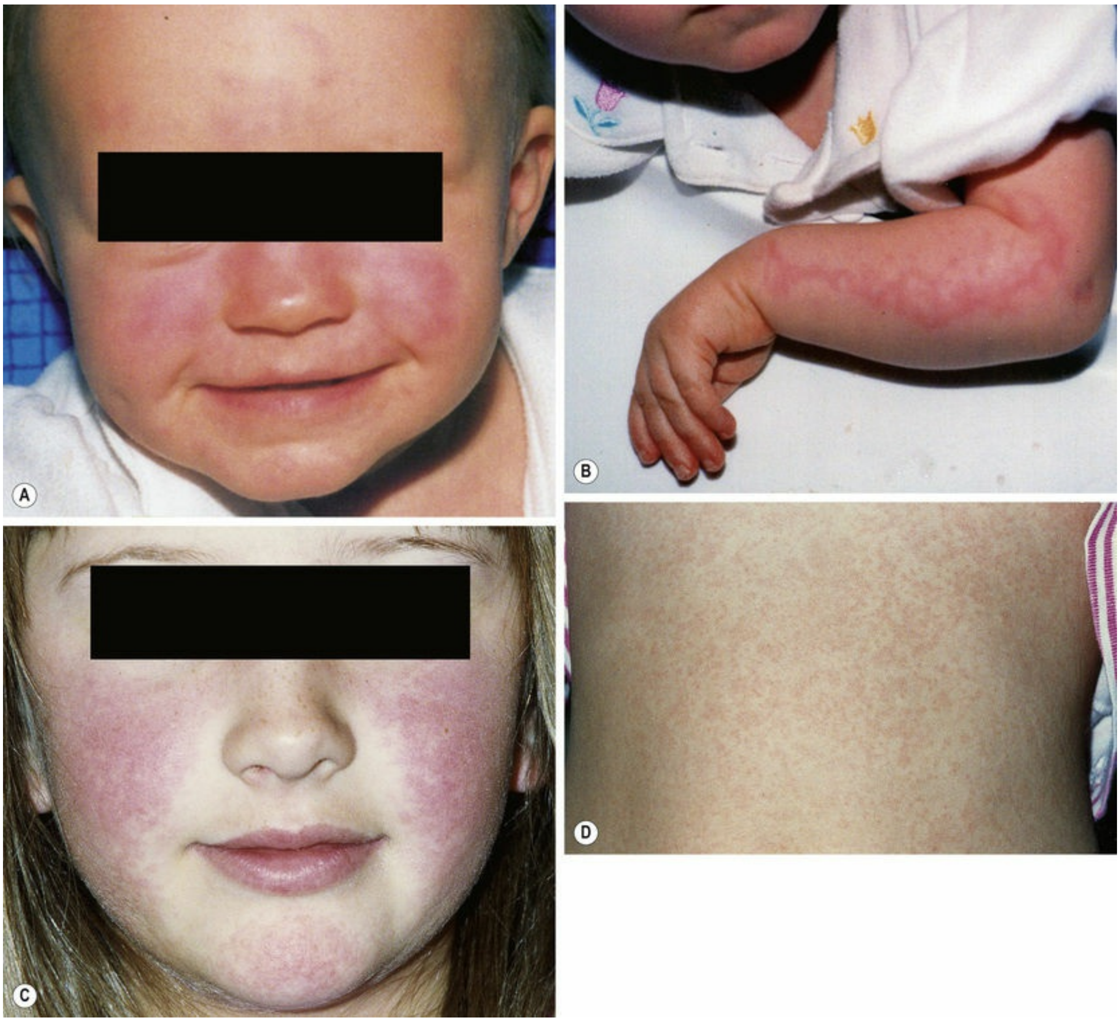

FIGURE 214.2 Toddler (A, B) and child (C, D) with typical exanthems of fifth disease. (Courtesy of J. H. Brien© and M. Prober.)

Polyarthropathy Syndrome

Although uncommon in children, arthropathy occurs in about 50% of adults and is more common in women than men.[37] The joint distribution often is symmetric, with arthralgia and even frank arthritis affecting the small joints of the hands and occasionally the ankles, knees, and wrists. Resolution usually occurs within a few weeks, but persistent or recurring symptoms can continue for years. Rarely B19V infection can be associated with chronic arthritides, including juvenile idiopathic arthritis.[38,39]

Transient Aplastic Crisis

Transient reticulocytopenia followed by rebound reticulocytosis occurs in most subjects infected with parvovirus B19.[40] This transient marrow suppression is not associated with symptoms in most individuals. However, among those who depend on continual rapid production of red blood cells, parvovirus B19 infection often causes transient aplastic crisis (see Fig. 214.1B).[25] Affected individuals include those with hemolytic disorders (e.g., hereditary spherocytosis), hemoglobinopathies (e.g., sickle-cell disease, thalassemia), red cell enzymopathies (e.g., glucose-6′-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, pyrimidine-5′ nucleotidase deficiency) and autoimmune hemolytic anemias.[41] Aplastic crises precipitated by parvovirus B19 infection often necessitate treatment with blood transfusions and can be associated with a high rate of severe complications.[42] Patients with aplastic crisis have high levels of viremia, have no rash, and are infectious at the time of clinical presentation.[43]

Chronic Bone Marrow Failure and Pure Red Cell Aplasia

Key Points

Immunocompromised or Immunosuppressed Children

Epidemiology

- Can be acquired from respiratory secretions, blood, and blood products

Clinical Features

- Infection manifests as severe anemia.

- Other bone marrow lineages also can be affected.

Diagnosis

- Absence of reticulocytes in peripheral blood and red cell precursors in bone marrow

- Quantitative polymerase chain reaction for high-level ($>10^6$ IU/mL) parvovirus B19 (B19V) DNA in peripheral blood

- B19V-specific immunoglobulin M (IgM) and IgG antibody can be low level or absent.

Treatment

- Immune globulin intravenous

Persistent B19V infection resulting in pure red cell aplasia has been reported in a wide range of immunosuppressed patients, including those with congenital immunodeficiency (e.g., Nezelof syndrome), acquired immunodeficiency syndrome, and lymphoproliferative disorders (especially acute lymphoblastic leukemia), as well as transplant recipients.[41,44] Patients manifest persistent anemia associated with reticulocytopenia, absent or low levels of parvovirus B19–specific antibody, and high concentrations of parvovirus B19 DNA in serum (see Fig. 214.1C). Bone marrow examination often reveals the presence of scattered giant pronormoblasts. Temporary reduction of chemotherapy may result in an immune response to parvovirus B19 and resolution of infection. Alternatively, administration of immunoglobulin can lead to a prompt drop in viral DNA titers in the blood and resolution of infection.[45,46]

Other Hematologic Complications

Although parvovirus B19 primarily targets the red cell precursor, other hematologic lineages can be affected. Transient neutropenia, lymphopenia, and thrombocytopenia have been observed during acute parvovirus B19 infection.[36,41] Parvovirus infection can be associated with a hemophagocytic syndrome,[47] idiopathic thrombocytopenia, Henoch-Schönlein purpura, and papular purpuric gloves and socks syndrome.[48,49]

Transient erythroblastopenia of childhood and aplastic anemia do not appear to be caused by the virus.

Unusual Manifestations

A large number of unusual clinical presentations associated with detection of parvovirus DNA in serum and tissue have been reported, including neurologic disease, myocarditis, kidney disease, hepatitis, and a wide range of vasculitides.[49] However, the observation that parvovirus B19 DNA can be detected by PCR for years in normal tissue in healthy individuals confounds conclusion of a causal role.[16,50] B19V infection appears to be causally associated with some cases of childhood myocarditis.[51]

Infection and the Fetus

Maternal infection with B19V during pregnancy can lead to miscarriage or the development of hydrops fetalis.[52,53] The risk for adverse outcome primarily is associated with maternal infection occurring during the first half of gestation. In a British study of 427 pregnant women who contracted B19V infection during gestation, excess fetal loss was observed only among those infected during the first 20 weeks of pregnancy. The observed risk for fetal hydrops was 2.9% (95% confidence interval, 1.2–5.9),[54] with no abnormalities found at birth in surviving infants. Similar findings have been found in studies in other countries.[55–58]

Parvovirus B19 probably causes approximately 10% of all cases of nonimmune hydrops.[59–61] The pathogenesis is a combination of cardiac decompensation due to severe anemia and B19V-induced fetal myocarditis. Many cases of B19V-induced hydrops fetalis are treated with intrauterine blood transfusion, with high rates of success.[62–65]

B19V does not appear to be teratogenic, although anecdotal reports of possible eye damage and central nervous system abnormalities in infants whose mothers were infected with parvovirus B19 during pregnancy have been reported,[66] and cases of congenital anemia following maternal gestational infection have been described.[67,68]

Diagnosis

Key Points

Children With Increased Red Cell Turnover

Epidemiology

- Can be acquired from respiratory secretions, blood, and blood products

Clinical Features

- Infection manifests as transient aplastic crisis.
- Infection usually is self-limited, with production of neutralizing antibody.
- Aplastic crisis can lead to severe complications and can be life-threatening.

Diagnosis

- Absence of reticulocytes in peripheral blood and red cell precursors in bone marrow
- Quantitative polymerase chain reaction for high-level ($>10^6$ IU/mL) parvovirus B19 (B19V) DNA in peripheral blood
- B19V-specific immunoglobulin M (IgM) and IgG antibody can be absent at diagnosis.

Treatment

- Symptomatic treatment with blood transfusion as necessary

Parvovirus B19 is difficult to isolate in culture. Detection of virus in serum, tissues, or cells depends on detection of viral DNA, generally quantitative PCR.

Diagnosis of erythema infectiosum generally is based on the detection of IgM antibodies, which are detectable at the time of onset of the rash (see Fig. 214.1) Commercial assays, based on recombinant virus-like particles are sensitive and specific. IgM antibodies remain detectable for 2 to 3 months after primary infection.

IgG antibodies are detectable at the same time as IgM antibodies and remain detectable for life. Because >50% of the population has parvovirus B19 IgG antibodies, the test is not as useful for diagnosis of acute infection but can be helpful in determining prior infection or excluding the diagnosis.

Quantitative PCR assays are highly sensitive and specific tests that can be used to identify acute and chronic B19V infection. Because B19V DNA can be detected by PCR for many months after acute infection, quantitative PCR is critical, and the viral load can be useful in estimating the time of infection.[69] In acute infection, viremia peaks at $>10^{12}$ parvovirus B19 DNA genome copies/mL of serum and falls rapidly within days. Patients with aplastic crisis or pure red cell aplasia due to parvovirus B19 generally have $>10^{6}$ parvovirus B19 DNA international units (genome copies)/mL of serum at the time of the crisis.

Treatment and Prevention

No antiviral drug is licensed for treatment of B19V infection, although cidofovir has antiviral properties in vitro.[70] Because the humoral immune response plays a prominent role in controlling parvovirus B19 infection, commercial immune globulin preparations from healthy blood donors can clear or ameliorate persistent parvovirus B19 infection in immunosuppressed patients.[46,71] Treatment of patients with polyarthropathy is symptomatic only; administration of immunoglobulin is not beneficial. Patients with chronic anemia due to B19V infection, including fetuses with hydrops fetalis, are treated with blood transfusions.

Patient with the rash of erythema infectiosum are no longer infectious and do not need to be isolated. In contrast, persons with transient aplastic crisis or chronic parvovirus B19 infection have high levels of viremia and are contagious. For hospitalized persons, Droplet Precautions, in addition to Standard Precautions, are recommended. The duration of these precautions depends on clinical presentation and immunologic competency.[72]

No vaccine is approved for parvovirus B19, although research for a candidate vaccines is ongoing.[73,74] A vaccine would be advantageous in specific populations where parvovirus B19 potentially can cause substantial morbidity, such as those who are pregnant, immunocompromised, or have underlying hemolytic disorders or increased red cell production.

RNA Viruses: Reoviridae

OUTLINE

215 Coltivirus (Colorado Tick Fever)
216 Rotaviruses

215

Coltivirus (Colorado Tick Fever)

J. Erin Staples, Marc Fischer

Colorado tick fever (CTF) is an acute febrile illness caused by the Colorado tick fever virus (CTFV). CTFV is a double-stranded RNA virus assigned to the *Coltivirus* genus of the family Reoviridae (Box 215.1).[1,2] The virus is transmitted to humans through the bite of an infected Rocky Mountain wood tick, *Dermacentor andersoni* (Fig. 215.1)

Box 215.1

Colorado Tick Fever: Agent and Epidemiology

Agent

Colorado tick fever virus, *Coltivirus* genus, Reoviridae family

Vector

Dermacentor andersoni, Rocky Mountain wood tick

Natural Reservoir

Rodent, small mammal–tick cycle

Distribution

Western United States and southwestern Canada at elevations from 4000 to 10,000 feet

Seasonality

March–September with an April–July peak

Risk Factors

Outdoor exposure in an endemic area

One transfusion-acquired case and 16 laboratory-associated cases reported

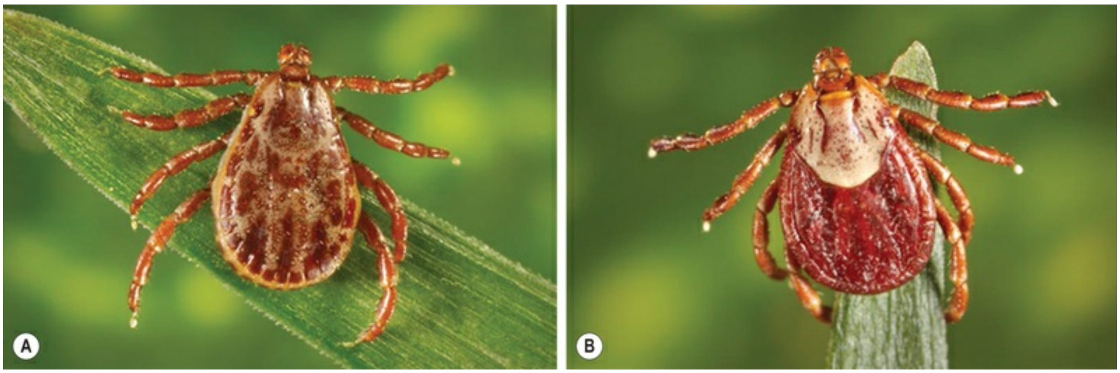

FIGURE 215.1 Both adult male (A) and female (B) *Dermacentor andersoni* ticks can transmit Colorado tick fever virus.

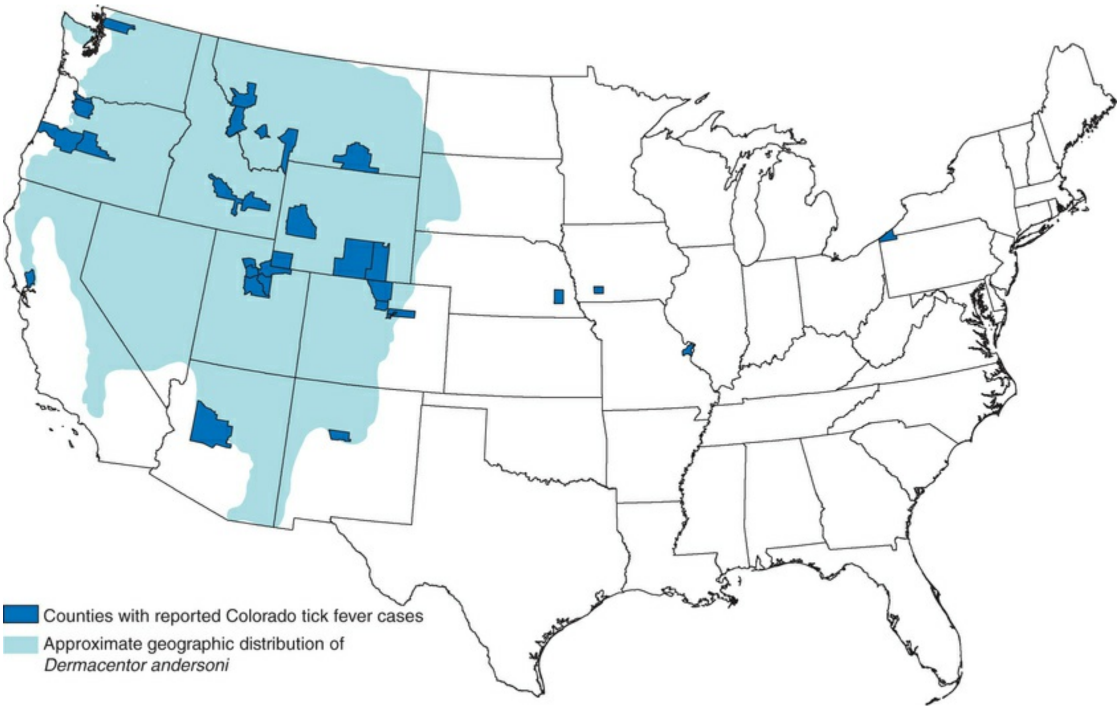
Tick Vector and Vertebrate Hosts

CTFV is maintained in an epizootic cycle between *D. andersoni* and small mammals, principally rodents.[3–13] The virus-amplifying mammal hosts develop apparently silent infections but remain viremic for weeks to months. Larval ticks become infected as a result of feeding on viremic mammals. Infection then passes from larval ticks to the nymphal and adult stages. Humans usually are infected by bites of adult ticks.[5,7,12]

Epidemiology

D. andersoni is found in the western United States and southwestern Canada at elevations from 4000 to 10,000 feet, typically in grassy areas near sage or other brush (Fig. 215.2).[3,8–12] Up to 90% of CTFV-infected persons report a recent history of tick bite or outdoor exposure in *D. andersoni*–endemic areas.[14–16] Most human cases occur between April and July.[14–17] Though CTF cases were originally reported more frequently among people aged 10 to 49 years, two recent studies found a higher proportion of CTF cases reported among adults aged ≥40 years.[14,16,17]



Counties with reported Colorado tick fever cases
Approximate geographic distribution of *Dermacentor andersoni*

FIGURE 215.2 Approximate geographic distribution of *Dermacentor andersoni* ticks and counties of residence for confirmed and probable Colorado tick fever virus disease cases, United States, 2002−2012. (*Light blue,* data from James AM, Freier JE, Keirans JE, Durden LA, et al. Distribution, seasonality, and hosts of the Rocky Mountain wood tick in the United States. J Med Entomol 2006; 43:17–24.)

CTF is not a nationally notifiable disease, but it is reportable in some states where the disease is endemic. From 2002 through 2012, 75 CTF cases were reported from 14 US state health departments, with Wyoming, Montana, and Utah reporting more than two thirds of cases (see Fig. 215.2).[17] These three states also had the highest annual incidence of reported CTF among residents, with 3.4 cases per million residents in Wyoming, 1.5 per million in Montana, and 0.5 per million in Utah.

From 1987 through 2001, a median of 55 CTF cases were reported in the United States.[8] However, that number declined consistently over the 15-year period, with a median of 80 cases annually from 1987 to 1994 and 18 cases per year from 1995 to 2001. From 2002 to 2012, the number of CTF cases has further declined, with a median of 5 cases per year.[17] This decrease in case counts over time likely reflects changes in testing and reporting practices. For example, Colorado historically reported the largest number of CTF cases.[8] However, CTF was not a notifiable condition in Colorado from 1997 to 2013, and during 2002 through 2012, Wyoming, Montana, Utah, and Oregon each reported more CTF cases than Colorado.[17] A survey in one endemic area suggested that only 10% of CTF cases were reported.[3] However, changes in the environment or human exposure also may have played a role.[9] One transfusion-acquired and 16 laboratory-associated cases of CTF have been reported.[18–23]

Clinical and Laboratory Findings

The incubation period for CTF is usually 3 to 4 days (range, 1−14 days).[3,14,15] Symptoms include fever, chills, headache, myalgias, and lethargy (Box 215.2).[14,15,24] Sore throat, vomiting, abdominal pain, and stiff neck are less common manifestations. Physical examination may reveal conjunctival injection, pharyngeal erythema, lymphadenopathy, or hepatosplenomegaly. A maculopapular or petechial rash has been reported in 5% to 16% of patients.[14,16,24]

Box 215.2

Colorado Tick Fever: Clinical Features

History

Recent tick bite or outdoor exposure in endemic areas within 2 weeks of illness onset

Incubation Period

Usually 3–4 days; range 1–14 days

Symptoms

Fever, chills, headache, myalgias, lethargy

Sore throat, vomiting, abdominal pain, and stiff neck are less common

Signs

Elevated temperature, conjunctival injection, pharyngeal erythema, lymphadenopathy, or mild hepatosplenomegaly

Maculopapular or petechial rash (5%–12% of cases)

Clinical Course

Fever and symptoms remit in 2–4 days

Recurrence of symptoms after 1–3 days (50% of cases)

Approximately 15%–30% of reported cases are hospitalized

Prolonged convalescence especially among persons >30 years old

Leukopenia is the most characteristic laboratory finding in CTF (Box 215.3).[14,24–26] There is often a relative lymphocytosis with atypical lymphocytes. Thrombocytopenia can occur.[15,27] CTFV infects erythrocytic precursors in the bone marrow. Although red blood cells remain infected for their lifespan, anemia is rare.[14,21,26,28] Patients with central nervous system involvement typically have lymphocytic pleocytosis and elevated protein in their cerebrospinal fluid.[15]

Box 215.3

Colorado Tick Fever: Complications, Laboratory Findings, and Diagnosis

Complications

Life-threatening complications and deaths rare and often associated with meningoencephalitis or disseminated intravascular coagulation

Hepatitis, pericarditis, myocarditis, pneumonitis, epididymo-orchitis also have been reported

Laboratory Findings

Leukopenia (2000–4000/mm^3) is the most characteristic laboratory finding

Relative lymphocytosis with atypical lymphocytes

Moderate thrombocytopenia (20,000–60,000/mm^3) common

Diagnosis

Viral isolation from whole blood or red blood cells

Immunofluorescent staining of peripheral blood smear

Reverse transcriptase-polymerase chain reaction (RT-PCR) assay on serum or whole blood

Serologic assays (e.g., indirect fluorescent antibody and plaque reduction neutralization)

About one half of all patients experience a biphasic illness. In these cases, symptoms remit after 2 to 4 days, but then recur 1 to 3 days later.[14,15,24] Patients often are bedridden, with 15% to 30% requiring hospitalization.[15–17] A prolonged convalescence characterized by weakness and fatigue is common but age dependent, with symptoms often continuing for >3 weeks in persons older than 30 years.[14]

Life-threatening complications and deaths due to CTF are rare; most fatalities have been associated with disseminated intravascular coagulation or meningoencephalitis.[3,13,15,17,24,29] Other reported complications include hepatitis, pericarditis, myocarditis, pneumonia, and epididymo-orchitis.[14,20,29–32] Teratogenic effects and fetal loss have been found in mice experimentally infected with CTFV, but this association has not been clearly established in humans.[3,33,34]

Diagnosis

A history of exposure to an enzootic location is the most helpful clue to the diagnosis. The differential diagnosis includes other vector-borne infectious diseases (e.g., tularemia, Rocky Mountain spotted fever, tickborne relapsing fever, and mosquito-borne arboviral fevers), and non–arthropod-borne infections such as enteroviruses and leptospirosis.[1,8] Distinguishing CTF from Rocky Mountain spotted fever can be difficult. However, a biphasic fever pattern, prominent leukopenia, and absence of a hemorrhagic rash all favor a diagnosis of CTF. The geographic distributions of other tickborne diseases such as human anaplasmosis (i.e., human granulocytic ehrlichiosis), human monocytic ehrlichiosis, and babesiosis have minimal overlap with that of CTF; therefore residence and travel history may help in the differentiation of these diseases.

CTFV can be isolated from whole blood or red blood cells in suckling mice or cell culture.[3,8,21,35] CTFV antigens also can be detected in peripheral blood smears by immunofluorescent staining.[36] Although culture and immunofluorescent staining are most sensitive during the acute illness, CTFV has been isolated from nearly 50% of patients 4 weeks after onset, and viral antigen can be detected in red blood cells in peripheral blood smears for up to 20 weeks.[14,21,35] Reverse transcriptase polymerase chain reaction (RT-PCR) assays can detect CTFV RNA in serum or whole blood reliably during the first 2 weeks of illness and for up to 6 weeks after onset.[17,37–39]

The most commonly used serologic assays for CTF are indirect fluorescent antibody and plaque-reduction neutralization testing.[1,37,40–42] Antibodies to CTFV are slow to develop, with <50% of patients having detectable antibodies by 2 weeks after illness onset.[17,40,41] However, by 30 days, >90% of patients have neutralizing antibodies, with titers peaking around 20 weeks after onset.[14,17] Other tests that have been used to detect CTFV antibodies include enzyme immunoassay (EIA), complement fixation, and Western blot. IgM antibodies measured by EIA usually do not appear until 14 to 21 days after illness onset and decline abruptly after 6 weeks.[1,40] Complement-fixing antibodies develop late after CTFV infection and are not detected in 25% of patients.[1,41]

Testing for CTFV and CTFV-specific antibodies are available only at a few laboratories. Many laboratory tests for CTF have not been adequately standardized or evaluated.

Treatment and Prevention

Patients with CTF should be given supportive care under standard infection control precautions. No specific therapy is available. Ribavirin variably inhibits CTFV growth in vitro,[43] but safety and efficacy data in humans are lacking. Patients with CTF should defer blood and bone marrow donation for at least 6 months after recovery.[8,21,44]

Residents or travelers with outdoor exposures in endemic areas should wear protective clothing, spray clothing with permethrin, apply repellent to exposed skin, and periodically check for and remove ticks.[3,8,10] CTFV should be handled under Biosafety Level 2 conditions to minimize risk for laboratory-acquired infection.[23]

Other Related Tickborne Coltiviruses

Historically, coltiviruses have been divided into subgroup A (North American and European species) and subgroup B (Asian species). However, the subgroup B mosquito-borne viruses were recently reassigned to a new genus designated *Seadornavirus* (Southeast Asian dodeca RNA virus).[1,45] One other tickborne coltivirus, Eyach virus, has been associated with human neurologic disease in Europe.[8,46–48]

Rotaviruses

Catherine Yen, Margaret M. Cortese

Before the availability of rotavirus vaccines, rotaviruses were the most common cause of severe infant and childhood gastroenteritis worldwide, responsible for 40% of all diarrheal hospitalizations and more than half a million deaths among children under 5 years of age annually.[1] To mitigate this substantial burden of disease, rotavirus vaccines have been developed and now are licensed in many countries. By 2016, 81 countries had introduced rotavirus vaccines in their national immunization programs, including 33 countries in Africa.[2]

Description of the Pathogen

Rotaviruses were first discovered in humans in 1973 when researchers identified wheel-shaped particles on electron microscopy of duodenal mucosa biopsies from infants with severe gastroenteritis (Fig. 216.1).[3,4] Rotaviruses are 100-nm, nonenveloped RNA viruses belonging to the family Reoviridae.[5,6] Viral particles contain a triple-layered capsid surrounding a viral genome of 11 segments of double-stranded RNA.[5] These RNA segments code for six structural proteins (VP1–VP4, VP6, and VP7) and six nonstructural proteins (NSP1–NSP6). The VP7 protein (a glycoprotein, or G-type protein) and VP4 protein (a protease-activated protein, or P-type protein) constitutes the outer layer of the capsid. These proteins are the principal targets of neutralizing antibodies and are critical to vaccine development. The VP6 protein makes up the middle layer of the capsid and is the protein to which common immune diagnostics are directed. The other three structural proteins make up the inner core of the capsid (VP2) or are associated with viral RNA (VP1 and VP3). The NSP4 protein is an enterotoxin that mediates some of the early symptoms and signs of disease and may be a protein to which antibodies are developed in the immune response to infection.[6]

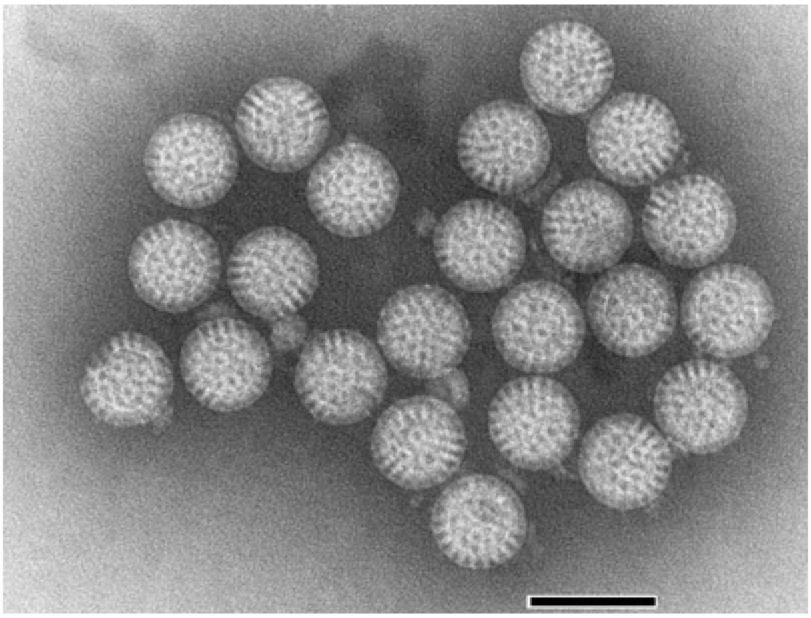

FIGURE 216.1 Electron micrograph of rotavirus particles in stool specimens, visualized by negative staining. Note typical double-shelled appearance of intact virions. Spikes formed by VP4 and protruding from the outer shell are not apparent in this image. (Courtesy of Charles D. Humphrey, PhD, Centers for Disease Control and Prevention, Atlanta, GA.)

Rotaviruses most commonly are classified according to group and serotype. Eight groups of rotavirus have been described (A–H) and are based on genetic and antigenic differences in the VP6 protein.[5] Only those viruses in groups A, B, and C are known to cause disease in humans. Group A rotaviruses are the principal cause of human disease and the main subject of this chapter. Group B rotaviruses have been associated with epidemic gastroenteritis in Asia,[7–9] and group C rotaviruses have been associated with sporadic mild gastroenteritis.[10–12] Of note, several animal species are susceptible to rotavirus infection (e.g., primates and cows).

However, the rotavirus strains that infect these animals differ from those that infect humans, and animal-to-human transmission appears to be uncommon.[13,14]

Group A rotaviruses are further classified by serotype based on their VP7 (G-type) and VP4 (P-type) proteins. G types commonly are determined by either enzyme immunoassay (EIA) using type-specific monoclonal antibodies for predominant serotypes or by reverse transcriptase polymerase chain reaction (RT-PCR).[13,15] P types usually are determined using molecular methods, such as RT-PCR or sequencing, because characterization by more traditional methods is difficult. To date, at least 27 G serotypes and 37 P genotypes have been described.[16] Globally, five G types (G1–G4 and G9) and three P types (P[4], P[6], and P[8]) predominate.[13,15–17] Although the genes that code for VP7 and VP4 segregate independently, five combinations of these common types generally account for 80% to 90% of circulating viruses: P[8]G1, P[4]G2, P[8]G3, P[8]G4, and P[8]G9.[17] Of note, certain histo-blood group antigens on enterocytes have been proposed as receptors or ligands for the P protein of rotaviruses and associations between a population's frequency of particular histo-blood group antigens and disease (or lack of disease) from particular rotavirus P genotypes have been made.[18–21]

Epidemiology

Rotaviruses are the most common cause of severe, dehydrating gastroenteritis among children worldwide.[22,23] However, the epidemiology of infection in different settings can be distinct. Before the availability of rotavirus vaccines, an estimated 527,000 children younger than 5 years died each year from rotavirus disease worldwide, accounting for about 40% of all diarrheal deaths and 5% of all deaths in this age group. More than 85% of these deaths occurred in low-income countries (Fig. 216.2).[1] Although rotavirus-associated deaths were rare in high-income countries, hospitalizations were common in both developed and economically developing countries.[24–27] In the United States, before implementation of the rotavirus vaccination program in 2006, rotavirus gastroenteritis accounted for 55,000 to 70,000 hospitalizations, 205,000 to 272,000 emergency department visits, and 410,000 physician visits annually, with total annual direct and indirect costs of about $1 billion.[28–32] Studies in countries in Asia estimate that about 24% to 50% of gastroenteritis hospitalizations are attributable to rotavirus.[33–37] These estimates are similar to those from Africa and during the prevaccine era in Latin America.[38,39]

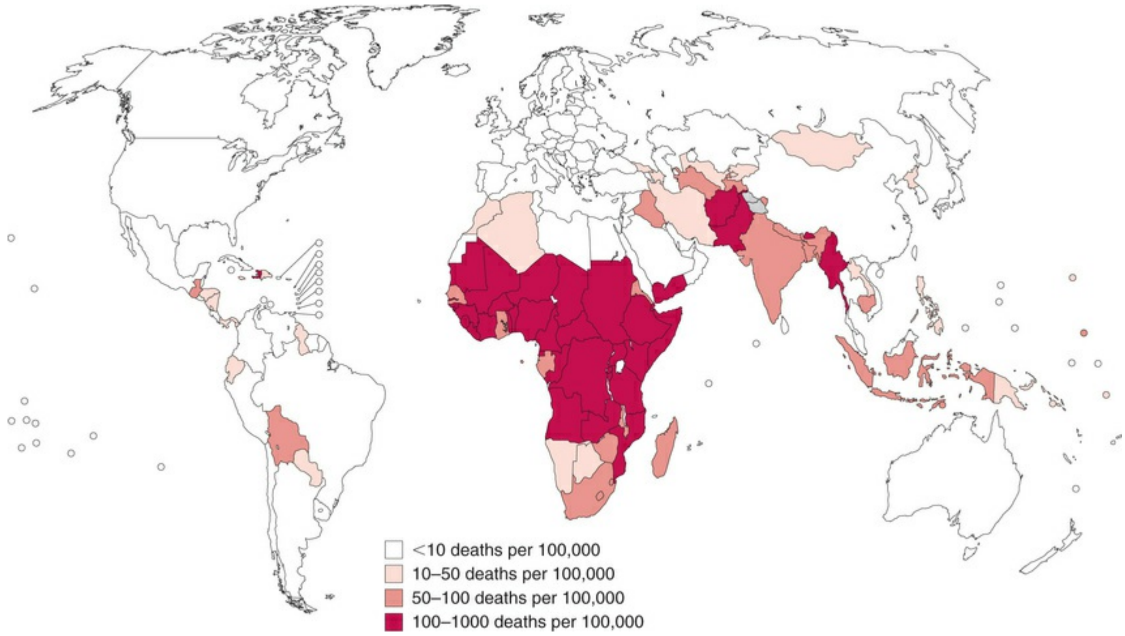

FIGURE 216.2 Estimated distribution of rotavirus deaths among children younger than 5 years, by country. (Adapted from Tate JE, Burton AH, Boschi-Pinto C, et al. 2008 Estimate of worldwide rotavirus-associated mortality in children younger than 5 years before the introduction of universal rotavirus vaccination programmes: a systematic review and meta-analysis. Lancet Infect Dis 2012;12:136−141.)

In temperate climates, rotavirus disease occurs in distinct winter seasonal peaks.[27,40–44] Before introduction of vaccine in the United States, rotavirus activity usually began in early winter in the Southwest and moved across the country, ending in northeastern states in the spring.[42] In tropical settings, rotavirus can circulate year-round, but often has seasonal peaks during the cool or dry months.[26,39,45,46] Rotaviruses are spread through fecal-oral contamination, predominantly by close person-to-person contact.[5] Spread also likely occurs through contaminated fomites, especially in out-of-homecare settings and hospitals.[47–49] Very few infectious virions are needed to cause disease in susceptible hosts.[50] Although probable waterborne transmission has been described, spread through food and water is likely to be rare.[51] Transmission through airborne droplets has been hypothesized because of rapid seasonal transmission through populations, but is not proved.[5,52]

In areas without rotavirus vaccine, almost all children are infected at least once with rotavirus by the age of 5 years.[53,54] The highest rates of rotavirus gastroenteritis occur among children 4 to 23 months of age, who also are more likely to experience severe, dehydrating rotavirus gastroenteritis.[53,55–57] Infants younger than 3 months have lower rates of infection, and full-term neonates are more likely to be asymptomatic when infected, possibly owing to protection from passively transferred maternal antibody.[58,59] After a single natural infection, 38% of children are protected against subsequent rotavirus infection, 77% are protected against subsequent rotavirus gastroenteritis, and 87% are protected against severe rotavirus gastroenteritis; second and third infections confer progressively greater protection against rotavirus gastroenteritis.[54] Because natural infection confers protection against subsequent infection and disease, symptomatic illness is less common among those older than 5 years.[54,58] Even so, rotavirus can cause gastroenteritis among older children and adults, often in households with young children, or among adults who care for young children with rotavirus.[60,61] Rotavirus outbreaks have been reported among elderly adults in residential facilities.[62]

Clinical Manifestations

Rotavirus infects the villus enterocytes of the proximal small intestine, leading to destruction of the absorptive enterocytes, downregulation of the expression of absorptive enzymes, functional changes in tight junctions between enterocytes, and production of an enterotoxin.[6] This leads to symptoms of gastroenteritis after a mean incubation period of 1 to 3 days.[5] The initial manifestations of illness are often fever and abrupt onset of vomiting.[63–68] Most children have profuse, frequent diarrhea that can occur 8 to 20 times per day. Vomiting often resolves in 1 to 3 days, whereas diarrhea can persist for 5 to 8 days.[22,69] Some children initially have fever without gastrointestinal tract symptoms.[69] Complications and fatalities are related almost exclusively to the adverse effects of dehydration, electrolyte imbalance, and acidosis. Symptoms and asymptomatic viral shedding can be prolonged in immunocompromised patients, such as those with primary immunodeficiencies and those who have undergone bone marrow or solid-organ transplantation.[70–73] Rotavirus infection does not appear to cause more severe disease in children infected with HIV.[74] An important feature of rotavirus is that it is associated with more severe gastroenteritis than other enteric pathogens and is more likely to result in dehydration.[66]

Rare cases of meningoencephalitis possibly due to rotavirus have been reported.[75] Other extraintestinal rotavirus manifestations have been described, including acute myositis, hepatitis, hemophagocytic lymphohistiocytosis, and polio-like paralysis, but their relationship to rotavirus infection remains unclear.[76] Rotavirus antigenemia and viremia have been identified in children with rotavirus disease, but the clinical significance of these findings is unclear.[77–79] Rotavirus has been detected in some surveys of children with intussusception, although the studies usually are uncontrolled and the results variable.[80] A large case-control study did not find an association between rotavirus infection and intussusception.[81] Rotavirus is not thought to be a principal cause of intussusception.[81,82]

Laboratory Findings and Diagnostic Tests

Stool examination from patients infected with rotavirus reveals watery or soft stools, which rarely have gross blood and usually are guaiac-test negative. Fecal leukocytes generally are not observed. Patients can demonstrate electrolyte abnormalities associated with accompanying dehydration.[64] Additionally, rotavirus causes a transient rise in serum hepatic enzyme levels in about two thirds of children hospitalized for rotavirus gastroenteritis.[83]

The diagnosis of rotavirus is primarily made by testing of fresh, whole stool samples using one of many available commercial kits that detect group A rotavirus antigen by EIA, immunochromatography, or latex agglutination.[84] EIA assays are the most widely used because of their high sensitivity and specificity.[84,85] Rotavirus can be detected in stool using EIA tests during the symptomatic period and immediately before onset and for days after resolution of symptoms.[86,87] Virus also can be identified in stool by electron microscopy, electrophoresis and silver staining, and RT-PCR assay for detection of viral RNA. RT-PCR is more sensitive than antigen detection for rotavirus infection but remains primarily a research tool.

Treatment

No specific therapies exist for rotavirus infection. Care requires assessment of hydration status, appropriate correction of fluid loss and electrolyte disturbances, and maintenance of adequate hydration and nutrition. Oral rehydration using appropriate solutions is sufficient for most patients. Intravenous rehydration is required for some patients. Continuation or early reintroduction of oral feeding according to management guidelines should be a priority.[88] Breastfed infants should continue to nurse on demand. Infants fed with formula should continue their usual formula immediately upon rehydration. Children receiving semisolid or solid foods should continue to receive their usual diet during episodes of diarrhea, although it may be useful to avoid substantial amounts of foods high in simple sugars (e.g., carbonated soft drinks, juice, gelatin desserts) because the osmotic content might worsen diarrhea. Human or bovine colostrum and human serum immunoglobulin contain antibodies to rotavirus and may be beneficial in decreasing or preventing rotavirus diarrhea, but these are not used in routine practice.[72,89–91]

Prevention

Rotavirus Vaccines

Live, orally administered rotavirus vaccines currently are the best strategy for prevention of rotavirus morbidity and mortality. The available rotavirus vaccines are attenuated strains given in multiple doses and are designed to replace a child's first exposure to wild-type rotavirus with exposure to strains that will not cause disease but will generate a protective immune response.[92] Distinct approaches to rotavirus immunization have been taken with respect to strain type (i.e., use of attenuated, human strains, nonhuman strains, and human-animal reassortants), the number of strains in a vaccine (monovalent vs. polyvalent), and the number of doses.[92,93] Two rotavirus vaccines are used in immunization programs globally: RotaTeq (RV5) (Merck) and Rotarix (RV1) (GlaxoSmithKline). Both are licensed for use in the US. In the US recommendations, for both vaccines, maximal age to give the first dose is 14 weeks, 6 days, and maximal age for last dose is 8 months, 0 days.

RV5 is a live, pentavalent human-bovine reassortant vaccine that contains five separate reassortant viruses, four expressing a unique human G-type protein (G1–G4) and one expressing a human P-type protein (P[8]).[94] The vaccine is given to infants in the US in three orally administered doses at ages 2, 4, and 6 months.[95] Before licensure, a large efficacy trial performed predominantly in the US and Finland demonstrated a vaccine efficacy of 74% against G1–G4 rotavirus gastroenteritis of any severity through the first full rotavirus season after vaccination. Efficacy was 98% against severe G1–G4 rotavirus gastroenteritis.[94] Vaccine trials performed in Africa and Asia where disease burden is higher demonstrated lower efficacy; vaccine efficacy against severe rotavirus gastroenteritis was 64% in a trial conducted in Ghana, Kenya, and Mali and 51% in a trial conducted in Bangladesh and Vietnam.[96,97] This lower efficacy is consistent with the performance of oral vaccines in developing country settings.[98] In these settings, the immune response to oral vaccines may be reduced because of higher levels of transplacental maternal antibody, micronutrient malnutrition (e.g., vitamin A and zinc), interfering gut flora, and the disease state of the infant (e.g., HIV infection or concomitant diarrhea).[98,99] Although in vitro data suggest that human milk fed at the time of oral rotavirus vaccine administration may interfere with vaccine taken by immune and nonimmune components of breast milk, withholding breastfeeding for 30 to 60 minutes before and after vaccination did not statistically significantly improve the immune response to oral rotavirus vaccines in three studies.[100–102]

RV1 is a live, monovalent vaccine that contains an attenuated, human P[8]G1 strain. The vaccine is given to infants in the US in two orally administered doses at 2 and 4 months of age.[95] Vaccine efficacy of the 2-dose series against severe rotavirus gastroenteritis through the first year of life was 85% in Latin America and 96% in Europe.[103,104] Efficacy against rotavirus disease of any severity was 87% in Europe. In both Latin America and Europe, efficacy against non-G1 strains was observed. Clinical trials conducted in Africa demonstrated lower vaccine efficacy against severe rotavirus gastroenteritis, ranging from 49% in Malawi to 77% in South Africa for the 2- and 3-dose arms combined.[105] Despite lower vaccine efficacy, the number of rotavirus cases prevented per 100 infants vaccinated was substantial: 7 cases per 100 vaccinated in Malawi and 4 cases per 100 vaccinated in South Africa.[105]

In 2010, porcine circovirus or porcine circovirus DNA was detected in both rotavirus vaccines. The US Food and Drug Administration and other agencies concluded that this was not a safety risk; both manufacturers are working to remove it.[106,107]

Vaccine Impact

Many countries have documented substantial declines in the burden of rotavirus disease shortly after rotavirus vaccine introduction. In the US, RV5 was licensed in 2006 and RV1 was licensed in 2008. Data from a national laboratory surveillance network have demonstrated delayed, shorter rotavirus seasons and a sustained reduction in the number of rotavirus antigen-positive tests through the 2013–2014 rotavirus season compared with prevaccine years (Fig. 216.3).[108] Additionally, many studies have observed substantial declines in diarrhea-related and rotavirus-specific healthcare visits (i.e., outpatient, emergency department, and hospitalizations) among children younger than 5 years after rotavirus vaccine introduction.[109–114] An estimated 177,000 fewer gastroenteritis-related hospitalizations occurred during the 4-year period of 2007–2011 compared with prevaccine seasons among children younger than 5 years.[113] Declines in disease have also been noted among older age groups who are age-ineligible to receive vaccine, suggesting possible indirect benefits of vaccination.[115–117]

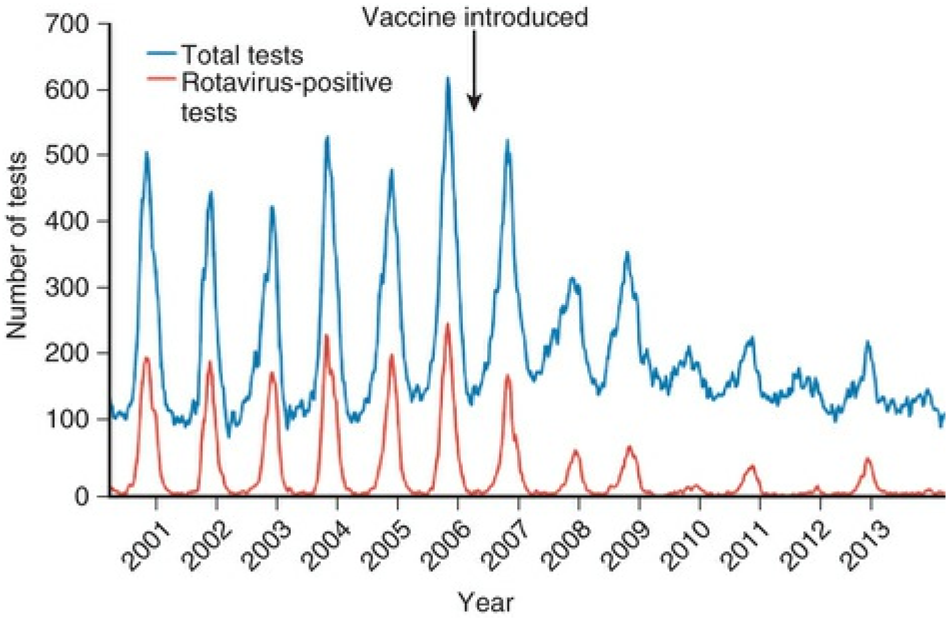

FIGURE 216.3 Number of total rotavirus enzyme immunoassay (EIA) tests performed and number of positive rotavirus EIA tests from 23 continuously reporting laboratories in the US National Respiratory and Enteric Viruses Surveillance System, by week of year, July 2000–August 2014, 3-week moving average. (Adapted from Aliabadi N, Tate JE, Haynes AK, et al. Sustained decrease in laboratory detection of rotavirus after implementation of routine vaccination: United States, 2000–2014. MMWR Morb Mortal Wkly Rep 2015;64:337−142.)

In Latin America, where rotavirus vaccines have been integrated into the national immunization programs of many countries since 2006–2007, reductions in both mortality and morbidity have been observed. In Mexico, sustained declines of 41% to 52% in diarrhea-related mortality rates among infants younger than 1 year were observed during the 3 years after rotavirus vaccine introduction in 2007 compared with prevaccine years.[118,119] Additionally, the number of diarrhea-related hospitalizations among infants in this age group decreased by 48% during 2008–2011.[120] In Brazil, a 25% to 39% reduction in diarrhea-related deaths, a 25% to 50% reduction in diarrhea-related hospitalizations, and an 82% decrease in rotavirus hospitalizations occurred among infants younger than 1 year after introduction of RV1.[121,122] In El Salvador in 2008 and 2009, a sustained decrease of >65% in the rate of rotavirus hospitalizations among children younger than 5 years was observed after introduction of RV1.[123]

In Australia, where both RV5 and RV1 were introduced in 2006, decreases of 50% to 93% in rotavirus hospitalizations among children younger than 1 year were observed during the 2 to 3 years after vaccine introduction.[124–127] Similar declines in rotavirus hospitalizations have been observed in several other high-income countries. For example, Austria, Finland, and Israel have documented reductions in rotavirus hospitalization rates of 72% to 88% among children younger than 1 year after vaccine introduction.[128–132]

Encouragingly, RV1 introduction in South Africa in 2009 resulted in at estimated 45% to 50% reduction in rotavirus hospitalizations among infants in first 2 years after introduction.[133] In Malawi, an estimated 43% reduction in the incidence of rotavirus hospitalizations among infants occurred in the second season after RV1 introduction in 2012.[134]

Vaccine Safety

Neither RV1 nor RV5 was found to be associated with intussusception in prelicensure trials.[94,103] Concerns that these vaccines might be associated with an increased risk for intussusception after vaccination are based on the demonstrated association between a previous quadrivalent, human-rhesus reassortant rotavirus vaccine (Rotashield, Wyeth Laboratories) and intussusception.[135,136] This vaccine was estimated to cause 1 excess case of intussusception per 10,000 vaccinated infants and was withdrawn from use in 1999, less than a year after being licensed and introduced in the US.[82,137] Postmarketing studies designed specifically to assess the association between receipt of RV5 or RV1 and intussusception have been conducted in Australia, Brazil, Mexico, and the US. Overall, data indicate that the available rotavirus vaccines are associated with a lower risk for intussusception than that seen with Rotashield—approximately 1 to 6 excess intussusception cases per 100,000 vaccinated infants.[138–142]

Considering currently available data that suggest a small risk of intussusception caused by rotavirus vaccine and considering that the benefits of rotavirus vaccination are great (>53,000 rotavirus hospitalizations and 14 deaths prevented by vaccination in one vaccinated birth cohort to age 5 years, versus 45–213 intussusception cases and <1 death potentially caused by vaccination), the Centers for Disease Control and Prevention continues to recommend both RV1 and RV5 to prevent severe rotavirus disease in US infants and children.[139]

Future Vaccines

Additional rotavirus vaccines are in various stages of development or licensure.[93,143] Although most are live, orally administered vaccines, parenterally administered vaccines also are being investigated.[92,143]

Other Preventive Measures

Nonvaccine approaches to prevention include breastfeeding and hand hygiene. Breastfeeding may protect young infants against rotavirus infection through antirotavirus antibodies and other nonimmunologic factors in human milk.[144] Appropriate hand hygiene practices should be encouraged, particularly in institutional settings such as childcare centers and hospitals.

Acknowledgment

Key Points

Epidemiology, Clinical Features, Diagnosis, Treatment, and Prevention of Rotavirus-Associated Gastroenteritis

Epidemiology

- Most common cause of severe, dehydrating gastroenteritis among children worldwide

- Can affect all age groups and areas in the United States

- Most children are infected at least once by the age of 5 years unless vaccinated.

▪ Highest rates of infection are among children 4 to 23 months of age.

- Main modes of transmission: fecal-oral contamination through person-to-person contact, contact with contaminated fomites; rarely foodborne or waterborne
- Infectious dose is as little as a few virions.

Clinical Features

- Mean incubation period: 1 to 3 days
- Main symptoms: watery diarrhea, fever, vomiting
- Potential complications: dehydration, electrolyte imbalance, acidosis, hepatitis; possibly meningoencephalitis (rare)
- Duration of illness: 3 to 8 days

Diagnosis

- Detection of rotavirus antigen in stool by enzyme immunoassay
- Sequencing by reverse transcriptase polymerase chain reaction testing to characterize strain type if needed

Treatment

- Replacement of fluid and electrolytes
- No antiviral drug available

Prevention

- Universal rotavirus vaccination during infancy

RNA Viruses: Togaviridae, Flaviviridae, and Bunyaviridae

OUTLINE

217 Togaviridae Alphaviruses
218 Flaviviruses
219 Bunyaviruses
220 Hepatitis C Virus
221 Rubella Virus

217

Togaviridae

Alphaviruses

J. Erin Staples, Ann M. Powers

Alphaviruses are arthropod-borne members of the family Togaviridae. They are small, enveloped RNA viruses.[1,2] Members of the western equine encephalitis virus, eastern equine encephalitis virus, and Venezuelan equine encephalitis virus serocomplexes cause encephalitis in horses and humans, whereas members of the Semliki Forest virus serocomplex, such as chikungunya, o'nyong-nyong, Mayaro, and Ross River viruses, cause epidemic fever and arthralgia.[3–5]

Viruses

Chikungunya Virus

Chikungunya virus is transmitted from one human to another primarily by infected *Aedes aegypti* and *Aedes albopictus* mosquitoes. Enzootic transmission cycles between forest-dwelling mosquitoes and wild mammals are documented in Africa.[6,7] Before 2013, chikungunya outbreaks were documented in countries in Africa, Asia, Europe, and the Indian and Pacific Oceans.[8] In 2013, the first locally acquired cases in the Americas were identified on islands in the Caribbean.[9] By the end of 2014, local transmission of chikungunya virus had been reported from 44 countries and territories in the Americas, with more than 1 million suspected cases reported.[10]

After an incubation period of 3 to 7 days (range, 2–12 days), chikungunya virus infection causes acute fever and polyarthralgia in most (72%–98%) infected persons.[11–17] Joint pains are usually bilateral and symmetric, and they can be severe and debilitating.[6,18] Other symptoms may include headache, myalgia, arthritis, conjunctivitis, vomiting, and maculopapular rash.[19–21] During large outbreaks of disease that occurred in and around the Indian Ocean from 2004 to 2007, a number of atypical disease manifestations were noted, including neurologic disease (e.g., meningoencephalitis, Guillain-Barré syndrome), eye and other organ involvement (e.g., uveitis, retinitis, hepatitis, nephritis, or myocarditis), and unusual dermatologic manifestations (e.g., bullous lesions).[18,22–30]

The acute symptoms of chikungunya typically resolve in 7 to 10 days. Mortality is rare and mostly occurs in older adults and those with underlying comorbidities.[23,31] Some patients have a relapse of rheumatologic symptoms, such as polyarthralgia, polyarthritis, tenosynovitis, or Raynaud syndrome, in the months following acute illness.[32] Studies have reported variable proportions (5%–60%) of patients with persistent joint pains lasting from months to years after their illness.[17,20,33–51]

There is no specific antiviral therapy to treat chikungunya virus infection. Treatment is palliative and includes rest, fluids, analgesics, and antipyretics.[11] In dengue-endemic areas, acetaminophen or paracetamol is the preferred first-line treatment for fever and joint pain to reduce the risk for hemorrhage until dengue can be ruled out. Persistent joint pain from chikungunya may be reduced by nonsteroidal antiinflammatory drugs, corticosteroids, or physiotherapy.[30,33,52]

Modes of transmission other than mosquitoes have been reported. Intrapartum transmission occurs in almost 50% of neonates when the mother was viremic around the time of delivery.[26,53,54] Infected neonates most commonly have had fever, pain, rash, and edema, but intracerebral and gastrointestinal hemorrhage and severe encephalopathy with seizures also have been reported.[25,26] In utero transmission has been reported in the second trimester associated with three miscarriages, in which chikungunya viral RNA was detected in fetal tissue.[26,55] Two small studies did not identify chikungunya virus or viral RNA in breast milk from viremic women, making transmission through breast milk less likely.[26,56] The virus has been transmitted through percutaneous needlestick and laboratory exposure to infected blood or virus culture.[57,58] Given that humans develop a high level of viremia, it is expected but not yet documented that transmission can occur through blood transfusions and organ or tissue transplantation.[59–64]

O'nyong-Nyong Virus

O'nyong-nyong virus and its variant virus, Igbo-Ora virus, are unusual among arboviruses in that they are transmitted between humans in Africa by infected anopheline mosquitoes, primarily *Anopheles funestus* and *Anopheles gambiae*, which also are vectors of malaria.[65,66] After an incubation period of about 8 days, the virus causes epidemic febrile polyarthralgia often accompanied by headache, pruritic rash, lymphadenopathy, and conjunctivitis.[67] There is no specific treatment; virtually all patients recover completely, but many are incapacitated for up to 2 weeks during the illness.[67] Mild or asymptomatic cases also may occur as indicated by the presence of o'nyong-nyong virus–specific antibodies in areas without epidemic disease transmission.[68]

Ross River Virus

Ross River virus is transmitted to humans in Australia and the Western Pacific by a broad range of mosquito vectors but primarily *Aedes vigilax, Aedes camptorhyncus, Aedes polynesiensis,* and *Culex annulirostris.*[69–72] The virus is transmitted enzootically between mosquitoes and kangaroos, horses, and other vertebrates; human-to-mosquito-to-human transmission also occurs.[70,73,74] One case of transfusion-associated transmission has been documented.[75] After an average incubation period of 7 to 9 days (range, 3–21 days), Ross River virus causes sudden onset of arthralgia, arthritis, rash, myalgias, fatigue, and fever to a variable degree.[69,72,73] Glomerulonephritis and suspected encephalitis have been reported rarely.[69,72] Disease affects primarily those between 20 and 60 years of age, whereas symptomatic illness is rare in children.[72,76,77]

Infection generally is not life-threatening, and symptoms usually resolve within 6 months.[69] Joint pain and inflammation can be treated with nonsteroidal anti-inflammatory drugs.[69,72]

Venezuelan Equine Encephalitis Virus

Venezuelan equine encephalitis virus is transmitted in tropical areas of the western hemisphere by a variety of mosquitoes, including *Psorophora confinnis, Psorophora columbiae, Aedes sollicitans, Aedes taeniorhynchus,* and *Culex (Melanoconion)* species.[78,79] Enzootic Venezuelan equine encephalitis virus strains are transmitted in sylvatic cycles between mosquitoes, primarily *Culex (Melanoconion)* species, and rodents; equines are the primary amplifying hosts for epizootic strains. Direct human-to-human transmission appears to be rare, but the virus has been isolated from the oropharynx of ill humans, aerosol transmission has occurred in laboratories, and the virus has been considered a possible bioterrorism threat.[78,80–82] After an incubation period of 2 to 5 days, Venezuelan equine encephalitis virus causes the abrupt onset of fever, headache, malaise, tremor, myalgia, nausea, and vomiting.[78,83,84] A high proportion of fatal cases in one epidemic had pneumonia.[85] During an outbreak in Colombia, <5% of all symptomatic infections were estimated to result in neurologic disease.[81] Two more recent studies of hospitalized patients infected with enzootic strains in Panama found that neurologic disease was seen most frequently in children.[83,84] Overall, the case-fatality rate for symptomatic disease is <1% but can be as high as 5% among patients who are hospitalized.[81,86,87]

Eastern Equine Encephalitis Virus

Eastern equine encephalitis virus is transmitted in enzootic cycles between mosquitoes and birds in wetland habitats of tropical and temperate areas of the western hemisphere. In eastern regions of North America, eastern equine encephalitis virus is maintained by the ornithophillic *Culiseta melanura* mosquitoes in an avian cycle. The virus is sporadically transmitted to horses and humans, which are dead-end hosts, by bridging mosquito vectors such as *Coquillettidia perturbans* and *Aedes vexans*.[88,89] In the southern United

States, reptiles may play a role in zoonotic maintenance of the virus.[90] The closely related Madariaga virus (previously known as South American strains of eastern equine encephalitis virus) has been found in *Culex* spp. (*Cx. pedroi* and *Cx. taeniopus*) and have been typically associated with equine disease.[91,92] However, several human disease cases associated with the Lineage III Madariaga viruses were identified in Panama during 2010.[84] The virus also has been experimentally transmitted to animals through aerosols.[93] After a typical incubation period of 5 to 8 days, eastern equine encephalitis virus causes the abrupt onset of fever, headache, vomiting, and diarrhea, followed by lethargy, weakness, paralysis, seizures, and coma.[84,88,89,94–96] The overall case-fatality rate is estimated to be 30% but has been reported to be as high as 75% in some case series, and survivors often have permanent neurologic damage.[84,89,94,97]

Other Alphaviruses of Medical Importance

A variety of other alphaviruses have been reported to cause either epidemic or sporadic illness in humans. Western equine encephalitis virus is transmitted between mosquitoes and birds in rural areas in the western hemisphere.[89] In recent years, western equine encephalitis virus disease in humans has not been documented despite continued enzootic transmission.[98–100] Aerosol transmission of western equine encephalitis virus in laboratories has been reported.[101] The risk for symptomatic infection, with manifestations ranging from mild febrile illness to meningitis or encephalitis, is highest in infants and young children.[88] Overall mortality is <5%; most adults recover completely, but children may have lasting neurologic sequelae.[3,88,89]

Sindbis virus has been reported from Europe, Africa, Asia, and Australia and has caused fever, rash, and arthritis.[1,102] Variants of Sindbis virus, including Ockelbo, Pogosta, and Karelian fever viruses, cause fever and arthralgia in Scandinavia and Russia.[1,102,103] Mayaro virus causes a febrile illness with rash and arthralgia in South America.[102,104] Barmah Forest virus disease appears to be similar to Ross River virus in its epidemiology and clinical manifestations and has resulted in small outbreaks of fever, arthralgia, arthritis, and rash in Australia.[102,105]

Laboratory Diagnosis

Routine clinical laboratory tests do not distinguish alphavirus infections from many other viral infections. Initial peripheral leukopenia with thrombocytopenia and eventual lymphocytosis occur.[106] Peripheral leukocytosis with a neutrophilic predominance is common with eastern equine encephalitis virus infection.[89] In patients with alphaviral encephalitis, cerebrospinal fluid (CSF) examination can show an initial neutrophilic and then lymphocytic pleocytosis; CSF protein is normal or elevated, and CSF glucose usually is normal.[88,89,107] Hyponatremia can develop in some cases due to inappropriate secretion of antidiuretic hormone.[89] A variety of abnormalities on brain imaging have been reported, but these are not pathognomonic.[26,27,94,108,109]

A specific diagnosis can be determined by finding virus, viral antigen, or viral RNA in serum, CSF, or tissues. However, most cases are diagnosed by detecting virus-specific immunoglobulin M (IgM) antibody in CSF or serum using an enzyme immunoassay or indirect immunofluorescent assay.[88,89] The IgM antibody assays usually distinguish between alphaviruses of different serogroups but can show occasional cross-reactivity for viruses of the same serogroup.[110] A fourfold or greater rise in specific neutralizing antibody titers between two serum samples obtained several weeks apart can confirm the infecting virus. Some alphaviruses, such as chikungunya and o’nyong-nyong viruses, can be identified in acute serum by real-time reverse transcriptase polymerase chain reaction or virus isolation.[6,111] Isolation of the neurotropic viruses from CSF is variably successful; tests for viral RNA in CSF are more sensitive.[112] Finally, immunohistochemical staining of fixed tissues can be performed to detect viral antigens. Diagnostic assays are available through many state health departments, a few commercial laboratories, and the Centers for Disease Control and Prevention.

Prevention

Alphavirus infection can be prevented by avoiding exposure to mosquitoes that transmit these viruses. Personal protective strategies include wearing repellent, staying in screened or air-conditioned dwellings, and avoiding outdoor activities during times when the vectors are most avidly seeking blood meals. Vaccines against Venezuelan equine encephalitis virus, eastern equine encephalitis virus, western equine encephalitis virus, and chikungunya virus have been used to protect laboratory workers and others with occupational exposure to these viruses.[113,114] In addition, one inactivated Ross River virus vaccine and several chikungunya virus vaccines are in various stages of clinical development.[114,115] However, no alphavirus vaccines are currently available for public use.

Key Points

Agents, Epidemiology, Clinical Features, Diagnosis, and Treatment of Alphavirus Infections

Agents

- Family Togaviridae; genus *Alphavirus*
- Arthritogenic viruses: Barmah Forest, chikungunya, Mayaro, o'nyong-nyong, Ross River, and Sindbis viruses
- Neurotropic viruses: Eastern equine encephalitis, Venezuelan equine encephalitis, and western equine encephalitis viruses

Epidemiology

- Transmitted to humans through the bite of various mosquito species
- Cause human disease throughout the world though specific viruses have regional distributions

Clinical Features

- Incubation period is typically a few days to a week.
- Two main clinical presentations:
  - Fever and polyarthralgia: acute onset of fever and joint pain, typically involving multiple joints

symmetrically

- Neuroinvasive disease: acute onset of fever and headache, often with abdominal symptoms; and progression to altered mental states, lethargy, and weakness, often with paralysis, seizures, and coma

- All ages can be infected, although more severe disease occurs in older adults and, for some viruses, in younger children and infants.

- Persons with less severe disease typically recover in 1 to 2 weeks.

- Morbidity can include permanent neurologic damage with neurotropic viruses and longer-term joint symptoms with arthritogenic viruses.

- Case-fatality rate varies by virus from rare (e.g., chikungunya virus) up to 30% (i.e., eastern equine encephalitis virus).

Diagnosis

- Most infections are diagnosed by serologic assays to detect virus-specific immunoglobulin M antibodies in serum or cerebrospinal fluid.

- Reverse transcriptase polymerase chain reaction testing of acute serum typically is positive with chikungunya and o’nyong-nyong viral infections.

- Immunohistochemistry can be used to test fixed tissues.

Treatment

- No specific antiviral drugs

- Supportive therapy including antipyrectic drugs, analgesics, and treatment of complications

Prevention

- No commercially available vaccines
- Personal protective measures to avoid mosquito bites:

Wear insect repellent

Stay in screened or air-conditioned dwelling

Wear long sleeves and pants

Flaviviruses

Susan L. Hills, Marc Fischer

The flaviviruses are single-stranded, enveloped RNA viruses that are transmitted to humans primarily through the bites of arthropods.[1] Although more than 40 arthropod-borne flaviviruses have been described, this chapter discusses those that are most important in causing human illness: yellow fever virus (YFV), dengue viruses, Japanese encephalitis virus (JEV), West Nile virus (WNV), tickborne encephalitis virus (TBEV), and Zika virus (ZIKV). Other flaviviruses not discussed in this chapter can cause sporadic or epidemic human illness and elicit cross-reactive antibody.

Specific Agents

Yellow Fever Virus

YFV, the prototype flavivirus, is transmitted to humans primarily by infected *Aedes* spp. and *Haemogogus* spp. mosquitoes in tropical areas of Africa and South America. Sporadic human infections occur after exposure to the enzootic mosquito vectors (*Haemogogus* spp. in South America and *Aedes africanus, Aedes furcifer, Aedes vittatus, Aedes luteocephalus,* and *Aedes simpsoni* in Africa).[2] These mosquitoes acquire YFV from infected monkeys and transmit the virus to humans who enter or live in the forest or savannah. Large urban outbreaks occur when viremic humans infect peridomestic *Aedes aegypti* mosquitoes, which can then transmit the virus to other humans. Direct person-to-person transmission of YFV has not been reported. However, the live, attenuated vaccine strain of the virus has been transmitted transplacentally, through breastfeeding, and through blood transfusion.[3–5]

Most YFV infections are asymptomatic. In symptomatic infection, after an incubation period of 3 to 6 days, yellow fever begins with the acute onset of fever, chills, headache, and myalgia, often accompanied by photophobia, back pain, anorexia, vomiting, and restlessness.[2,6] During this phase, patients are viremic. Viremia usually clears about 4 days after illness onset, as fever and other symptoms subside. Most patients remain anicteric and then fully recover. However, about 15% of all infected people develop severe yellow fever with jaundice.[7] After a brief remission lasting from a few hours up to 2 days, these patients have a recurrence of initial symptoms with progression to jaundice and sometimes hemorrhagic symptoms, including epistaxis, gingival bleeding, hematemesis, hematuria, or melena.[2] Patients can develop dysfunction of multiple organs, including the hepatic, renal, and cardiovascular systems. Viral invasion of the central nervous system is rare, but neurologic manifestations can include delirium, convulsions, and coma. Laboratory abnormalities include elevated aspartate and alanine aminotransferases, proteinuria, thrombocytopenia, leukopenia, and prolonged blood coagulation.[8] Complications include bacterial pneumonia and parotitis.[2] Most persons with mild yellow fever recover without long-term sequelae. For those with severe disease involving hepatorenal dysfunction, the case-fatality rate ranges from 20% to 50%.

The treatment of yellow fever is supportive and based on symptoms and organ systems involved. Supportive care should include maintenance of nutrition, optimization of fluid and metabolic balance, nasogastric suction to prevent gastric distention and aspiration, treatment of bleeding with fresh frozen plasma, and treatment of secondary infections as necessary.[2] Although multiple drugs have been evaluated or used empirically to treat yellow fever, to date, none has demonstrated specific benefit.[9]

An effective live, attenuated yellow fever vaccine has been available since 1937 and is recommended for persons 9 months and older who reside in or travel to endemic areas.[10] The vaccine is contraindicated in infants younger than 6 months and should only be given to infants aged 6 to 8 months when the risk for yellow fever outweighs the risk for adverse events in this age group.[10] In children aged 9 months and older, serious adverse events are rare but have been described, including cases of neurotropic and viscerotropic disease. The vaccine virus can be transmitted transplacentally and through breastfeeding.[3,4,10] Limited data suggest that vaccination during pregnancy does not increase the risk for congenital malformations or other adverse pregnancy outcomes. However, three infants developed encephalitis after being exposed to yellow fever vaccine virus through breastfeeding.[4,10,11] Thus, yellow fever vaccine should not be given to pregnant or breastfeeding women unless they have a clear risk for acquiring yellow fever.[10]

Dengue Viruses

There are four dengue virus (DENV) types, designated as DENV-1, DENV-2, DENV-3, and DENV-4; all are transmitted to humans through the bite of *Aedes* spp. mosquitoes, most frequently *A. aegypti* and *Aedes albopictus.*[12] Infection with any of the DENVs produces long-term immunity specific to the infecting DENV. Cross-protective heterotypic immunity usually is short-term. Dengue occurs throughout the tropics worldwide.[13] In the United States, DENV transmission has occurred in Texas, Hawaii, and Florida.[14–16]

The incubation period of dengue usually is from 3 to 10 days.[17] About 75% of infections with dengue viruses are asymptomatic or cause a relatively mild febrile illness. Previously, three overlapping syndromes of dengue were described: dengue fever, dengue hemorrhagic fever, and dengue shock syndrome. However, recent World Health Organization (WHO) guidelines have modified the clinical classification of dengue into three revised categories: dengue, dengue with warning signs, and severe dengue.[18] Dengue can be acutely incapacitating but is self-limited and usually resolves within 7 days without sequelae. Severe dengue, which occurs in about 5% of clinically apparent cases in endemic areas, is manifest by one or more of the following: severe plasma leakage, leading to shock or fluid accumulation with respiratory distress; severe hemorrhage; or severe organ dysfunction. If not appropriately treated, severe dengue has a case-fatality rate of up to 5%.[18,19] Secondary infection with a different DENV has been associated with increased risk for developing severe dengue.[18] Rarer manifestations of dengue include hepatitis, myocarditis, and encephalitis.[18]

Current WHO guidelines divide the clinical course of dengue into three phases: febrile, critical, and convalescent.[18] The acute febrile phase typically begins abruptly with high-grade fever. Other symptoms include headache, retro-orbital pain, myalgia, anorexia, nausea, vomiting, arthralgia, facial flushing, maculopapular rash, and conjunctival injection. Many patients with dengue have a positive tourniquet test (appearance of ≥10 petechiae in a 2.5-cm square patch of skin after inflation of a blood pressure cuff), and about 25% have mild hemorrhagic manifestations such as epistaxis or gum bleeding. Common laboratory abnormalities include thrombocytopenia, leukopenia, hyponatremia, and elevated aspartate and alanine aminotransferases. Differentiating acute phase dengue from other acute febrile illnesses is difficult, and the discriminating manifestations may vary with age. In a report from one endemic area, the presence of retro-orbital pain was predictive of laboratory-confirmed dengue in patients of all ages, whereas rash was predictive of dengue only in patients older than 9 years.[20] Leukopenia was predictive of dengue in patients older than 20 years, whereas thrombocytopenia was predictive for those older than 10 years.

The critical phase of dengue commences in the 24 to 48 hours after defervescence, which typically occurs 2 to 7 days after illness onset. At this point, most patients improve, and their illness resolves. Warning signs for development of severe dengue include abdominal pain, persistent vomiting, extravascular fluid accumulation, severe mucosal bleeding, lethargy, restlessness, hepatomegaly, and increasing hematocrit with decreasing platelet count.[18] A chest radiograph or abdominal ultrasound may reveal pleural effusion or ascites. Plasma leakage can progress to shock, often associated with narrowed pulse pressure and disseminated intravascular coagulation.[18] In rare cases, severe hemorrhage or critical organ dysfunction occurs without evidence of plasma leakage or shock.[18] Detailed WHO guidelines for treatment and management of severe dengue with carefully monitored intravenous fluid administration are available.[20a] The case-fatality rate of severe dengue can be reduced to <0.5% with early detection and appropriate fluid management.[18,21]

The critical phase of dengue usually resolves within 48 hours, and patients enter the convalescent phase. This phase is characterized by reabsorption of extravascular fluid over 2 to 3 days, typically with diuresis.[18] Some patients develop a confluent erythematous rash with "isles of white," pruritus, bradycardia, or electrocardiographic abnormalities during this phase.[18] Pulmonary edema or congestive heart failure can occur, particularly with excessive fluid administration.[18]

Patients with dengue who do not have warning signs or other indications for hospitalization can be managed as outpatients with rest, vigilant monitoring of clinical parameters, attention to hydration, and pain management with acetaminophen.[18] Aspirin and other nonsteroidal anti-inflammatory drugs should be avoided because of increased risk for bleeding.[18] WHO provides more detailed guidelines for management of nonsevere dengue as well as criteria for hospitalization,[20a] and the Centers for Disease Control and Prevention (CDC) has an online clinical case management course (http://www.cdc.gov/dengue/).

Congenital DENV infection has been described, but accurate estimates of the risk for maternal-fetal transmission are not available.[22] Some studies have suggested that maternal dengue infection during pregnancy might increase the risk for preterm birth and low birth weight.[22] Neonates with congenital dengue have had clinical manifestations ranging from fever with thrombocytopenia to pleural effusions, severe hemorrhage, and shock.[22]

Several dengue vaccines are in clinical trials, but none is available commercially at this writing.[23]

Japanese Encephalitis Virus

JEV is the leading vaccine-preventable cause of encephalitis in Asia. Japanese encephalitis (JE) occurs throughout most of Asia and parts of the Western Pacific.[24,25] JEV is maintained in an enzootic cycle between mosquitoes and amplifying vertebrate hosts, primarily pigs and wading birds.[26,27] The virus is transmitted to humans through the bites of infected mosquitoes. Humans usually do not develop a level or duration of viremia sufficient to infect mosquitoes and, therefore, are dead-end hosts.[28,29] Direct person-to-person spread of JEV does not occur except rarely through intrauterine transmission.[30,31] *Culex* spp. mosquitoes, especially *Culex tritaeniorhynchus,* are the principal JEV vectors.[26,32] The risk for JE is increased in rural areas with irrigated fields and where pigs are raised close to human dwellings.[33] In temperate areas of Asia, transmission is seasonal, and human disease usually peaks in summer and fall.[26,27,34] In the subtropics and tropics, seasonal transmission varies with monsoon rains and irrigation practices and may be extended or even occur year-round. Most JE cases occur among children, but in areas of recent viral introduction or where population immunity has waned, adults also develop the disease.[26,27] For most travelers to Asia, the risk for JE is very low but varies on the basis of destination, duration, season, and activities.[24] From 1973 through 2013, 68 JE cases among travelers or expatriates from nonendemic countries were published in the literature or reported to the CDC.[25,35]

Most human JEV infections are asymptomatic; <1% of infected people develop clinical disease.[27,34] Acute encephalitis is the most commonly identified clinical syndrome; aseptic meningitis and undifferentiated febrile illness also can occur but have been reported more commonly among adults.[27,36,37] Among patients who develop clinical symptoms, illness usually begins with acute onset of fever, headache, and vomiting, after an incubation period of 5 to 15 days. Mental status changes, seizures, focal neurologic deficits, generalized weakness, parkinsonism, and other movement disorders often develop over the next few days.[38] Acute flaccid paralysis, with clinical and pathologic features similar to poliomyelitis, also has been associated with JEV infection.[39] Laboratory findings can include a moderate leukocytosis, mild anemia, and hyponatremia.[36,37] Cerebrospinal fluid (CSF) typically shows a mild to moderate pleocytosis with a lymphocytic predominance, slightly elevated protein, and normal glucose concentration. The case-fatality rate is approximately 20% to 30%.[36] Among survivors, 30% to 50% have significant neurologic, cognitive, or psychiatric sequelae.[24] There is no specific treatment.[40] Supportive care includes maintenance of adequate cerebral perfusion and management of increased intracerebral pressure, aspiration, seizures, hypoglycemia, hyponatremia, and secondary infections.[38]

One JE vaccine, the inactivated Vero cell culture−derived vaccine Ixiaro (Valneva Scotland Ltd, Livingston, UK), is available in the US.[24] Ixiaro was licensed in March 2009 for use in persons 17 years and older and in 2013 for use in children 2 months through 16 years of age.[41] The primary series for Ixiaro is 2 intramuscular doses administered 28 days apart. For children aged 2 months through 2 years, each dose is 0.25 mL, and for adults and children 3 years and older, each dose is 0.5 mL. JE vaccine is recommended for travelers who plan to spend a month or longer in endemic areas during the JE virus transmission season. JE vaccine should be considered for short-term (<1 month) travelers whose itinerary or activities might increase their risk for exposure to JEV. Other inactivated and live, attenuated JE vaccines are available in Asia and Australia but are not licensed for use in the US.

West Nile Virus

WNV is transmitted primarily through the bite of several *Culex* spp. mosquitoes.[42] WNV is found in many parts of Africa, Asia, Australia, Europe, and North America and in some areas of Latin America. After the first detection of WNV in the Western Hemisphere in New York City in 1999, the virus spread over the entire continental US, with most intense transmission occurring in the central and western Great Plains states.[43]

Mosquitoes that acquire WNV from birds incidentally infect humans.[42] In immunocompetent people, viremia usually lasts <7 days, and viral concentrations in blood are too low to effectively infect mosquitoes. However, WNV can be transmitted through transfusion of infected blood and organ transplantation.[44–49] Screening of blood donations for WNV began in 2003 and has substantially reduced the risk for transmission through transfusion, but rare instances of breakthrough transmission can occur.[50,51] Occupationally acquired WNV infection has raised the possibility of aerosol transmission.[52,53]

Transplacental transmission of WNV and possible transmission through breastfeeding have been described but appear to occur infrequently.[54–56] Most women known to have been infected with WNV during pregnancy have delivered infants without evidence of infection or clinical abnormalities.[56] In the best-documented case of congenital WNV infection, the mother developed neuroinvasive WNV disease during the 27th week of gestation, and the infant was born with cystic destruction of cerebral tissue and chorioretinitis.[57] One infant who apparently acquired WNV infection through breastfeeding remained healthy.[58]

Most WNV infections are asymptomatic.[59–61] After an incubation period of 2 to 14 days, about 20% to 30% of infected people develop a systemic febrile illness (i.e., West Nile fever). Less than 1% of infected people develop neuroinvasive disease (e.g., meningitis, encephalitis, or acute flaccid paralysis).[59–61] The risk for neuroinvasive disease is highest in elderly people and in solid-organ transplant recipients.[62–66] From 2003 to 2012, a total of 13,108 WNV neuroinvasive disease cases were reported in the US.[67] Of these, 505 (4%) occurred in children, for an average annual incidence of 0.68 cases per 1 million children. Half of the pediatric cases (295) were classified as meningitis, 236 (47%) as encephalitis, and 14 (3%) as acute flaccid paralysis. For up-to-date WNV surveillance data, see http://www.cdc.gov/ncidod/dvbid/westnile/index.htm.

Patients with WNV nonneuroinvasive disease typically have an abrupt onset of fever, headache, myalgia, and weakness, variably accompanied by abdominal pain, nausea, vomiting, diarrhea, and a maculopapular rash.[68,69] The acute phase of illness usually resolves within several days, but fatigue, malaise, and weakness can linger for weeks. Patients with neuroinvasive disease can present with neck stiffness and headache, mental status changes, movement disorders such as tremor or parkinsonism, seizures, or acute flaccid paralysis with or without meningitis or encephalitis.[68–71] CSF reveals neutrophilic pleocytosis early in the infection evolving over several days to lymphocytosis.[72,73] Isolated limb paralysis can occur without fever or apparent viral prodrome.[71,74] Flaccid paralysis caused by WNV infection is similar clinically and pathologically to poliomyelitis caused by poliovirus, with damage of anterior horn cells.[71,75] Progression can occur to respiratory muscle paralysis requiring mechanical ventilation. Guillain-Barré syndrome can follow WNV infection and can be distinguished from anterior horn cell damage by CSF findings of elevated protein with few white cells and electrophysiologic findings indicating damage to peripheral myelin. Chorioretinitis, cardiac dysrhythmias, myocarditis, rhabdomyolysis, optic neuritis, uveitis, orchitis, pancreatitis, and hepatitis have been reported.[43,71,76] The mortality rate after WNV neuroinvasive disease in adults is about 10%; the case-fatality rate for neuroinvasive disease in children in the US is <1%.[43,77]

Clinical management of WNV disease is supportive. No antiviral or adjunctive therapies are approved or recommended for treatment.[78–80] There are numerous case reports and case series regarding the use of various products; however, the studies often had small sample sizes, and the results from some of the clinical trials have not been published. Because polyclonal immune globulin and interferon α-n3 are available, some physicians have chosen to use them to treat transplant recipients and other severely immunocompromised patients, but there is no proven benefit.[43,78,79,81] No vaccine is licensed for humans. Despite development of several vaccine candidates, phase 3 clinical trials have not been initiated because of the uncertain market potential and logistical difficulties in conducting these trials.[43,79]

Tickborne Encephalitis Virus

Tickborne encephalitis (TBE) is endemic in focal areas of Europe and northern Asia, with approximately 5000 to 13,000 cases reported annually.[82,83] TBEV infections are usually acquired in forested areas during outdoor occupational or recreational activities. Most cases occur from April through November, with peaks in early and late summer. The incidence and severity of disease are highest in persons older than 50 years.[84,85]

There are three subtypes of TBEV: European, Siberian, and Far Eastern.[84] Each is transmitted to humans through the bite of an infected *Ixodes* spp. tick, primarily *Ixodes ricinus* (European subtype) or *Ixodes persulcatus* (Siberian and Far Eastern subtypes). TBEV transmission can also occur through ingestion of unpasteurized dairy products, slaughtering viremic animals, and laboratory exposure.[84,86–88] Direct person-to-person spread of TBEV does not occur except rarely through blood transfusion or breastfeeding.[84]

About two thirds of TBEV infections are asymptomatic.[89,90] In people who develop clinical illness, the median incubation time is about 8 days (range, 2–28 days).[84,87,88,91] Typically, patients infected with the European subtype have a biphasic illness.[85,92] The first (viremic) phase consists of a nonspecific febrile illness, often followed by a remission of symptoms. About one third of these patients then develop the second, more severe (neuroinvasive) phase of illness, resulting in meningitis (about 50%), encephalitis (about 40%), or myelitis (about 10%).[85,92] Laboratory abnormalities include leukopenia and thrombocytopenia in the first stage, followed by leukocytosis in the second stage, and pleocytosis that can be polymorphonuclear progressing to monocytic, with elevated CSF protein.[84,85] The case-fatality rate associated with the European and Siberian subtypes is 1% to 3%. The Far Eastern subtype typically causes a more severe monophasic illness with a case-fatality rate of about 20% and neurologic sequelae in up to 80% of survivors. Most children with TBE recover without severe sequelae; however, residual problems, including cognitive deficits, headache, fatigue, and irritability, have been reported 2 to 7 years after acute illness.[93]

There is no specific antiviral treatment; therapy consists of supportive care and management of complications.[84] No TBE vaccines are licensed in the US.[82] Two safe, effective inactivated TBE vaccines are available in Europe, in adult and pediatric formulations: FSME-IMMUN (Baxter, Austria) and Encepur (Novartis, Germany).[82,91,94] Two other inactivated TBE vaccines are available in Russia: TBE-Moscow (Chumakov Institute, Russia) and EnceVir (Microgen, Russia).[82,91,94] Immunogenicity studies suggest that the vaccines should provide cross-protection against all three TBE virus subtypes.[82,91,94] Although no formal efficacy trials of these vaccines have been conducted, indirect evidence suggests that their efficacy is higher than 95%.[82,91]

Zika Virus

For several decades after ZIKV was first isolated from a monkey in Uganda in 1947, only sporadic human cases were reported from Africa and Asia.[96,97] In 2007, the first documented ZIKV outbreak was reported in Yap State, Federated States of Micronesia, and subsequently outbreaks were identified in Southeast Asia and the Pacific Islands.[98] In May 2015, the WHO reported the first local transmission of ZIKV in the Region of the Americas, with autochthonous cases identified in Brazil.[99] By December 2015, the Brazilian Ministry of Health estimated that 440,000 to 1,300,000 suspected cases of ZIKV disease had occurred in Brazil, and there had been further spread to many other countries.[100] Evidence suggesting an association of ZIKV infection with an increased risk for neonatal malformations and neurologic disorders prompted the WHO to declare the ZIKV outbreak a Public Health Emergency of International Concern on February 1, 2016.[101] By the end of 2016, local transmission had been reported in 48 countries or territories in the Americas. In the US between January 1, 2015 and June 8, 2016, 691 travel-associated cases had been reported from the 50 US states. In July 2016, local mosquito-borne transmission was reported for the first time in the US, in the state of Florida.

The primary mode of transmission of ZIKV is through the bite of an infected *Aedes* spp. mosquito. Other documented modes of transmission include intrauterine, intrapartum, and sexual transmission, and through laboratory exposure and blood transfusion.[102,103] Other theoretical modes include through breast milk and organ or tissue transplantation.

Most people infected with ZIKV do not develop symptoms. Characteristic clinical findings in patients who have symptoms are acute onset of fever with maculopapular rash, arthralgia, or conjunctivitis. Other commonly reported symptoms include myalgia, headache, retro-orbital pain, edema, and vomiting. ZIKV is transmitted in similar areas as dengue and chikungunya viruses, and it is difficult to distinguish diseases caused by these viruses on clinical features alone. ZIKV disease usually is mild, with symptoms lasting several days to weeks; hospitalization is uncommon; and the case-fatality rate is low. However, more severe presentations have been recognized, including severe thrombocytopenia, Guillain-Barré syndrome, meningoencephalitis, and acute myelitis.[102,104,105] Congenital ZIKV infection is of particular concern. The full spectrum of fetal and infant outcomes as a result of symptomatic or asymptomatic ZIKV infection in pregnant women is yet to be determined. An association between ZIKV infection and microcephaly has been confirmed, and additional severe brain, ocular, and other abnormalities have been reported.[106–109]

Prevention measures focus on avoidance of mosquito bites. Vaccine candidates are under development. Because of the potential severity of congenital ZIKV infection, the CDC recommends that all pregnant women consider postponing travel to areas where ZIKV transmission is ongoing. In addition, couples in which a woman is pregnant and the man has traveled to an area with active ZIKV transmission should use condoms or abstain from sex for the duration of the pregnancy. Prevention guidelines for other couples concerned about sexual transmission are also available[109] (http://www.cdc.gov/zika/transmission/sexual-transmission.html).

Persons with an illness consistent with ZIKV infection and possible exposure to ZIKV, including travel to an area with ZIKV transmission or sex without a condom with a man who traveled to an area of transmission, can be tested for ZIKV infection. Testing also can be considered for symptom-free pregnant women with possible exposure to ZIKV. Molecular and serologic testing methodologies are available for diagnosis; the appropriate test depends on the timing of possible exposure and symptom onset (http://www.cdc.gov/zika/hc-providers/diagnostic.html). No specific antiviral treatment is available. Treatment of symptoms may include rest, fluids, antipyretics, and analgesics. Aspirin and other nonsteroidal anti-inflammatory drugs should be avoided until dengue can be ruled out to reduce the risk for hemorrhage. In pregnant women with laboratory evidence of ZIKV virus infection, serial ultrasound examination should be considered to monitor fetal growth and anatomy, and referral to a maternal-fetal medicine or infectious diseases specialist is recommended. The CDC has developed guidelines for testing and management of pregnant women carrying a possibly infected fetus. Because maternal-infant transmission of ZIKV during delivery is possible, acute ZIKV disease should be suspected in an infant during the first 2 weeks of life who has a consistent illness and whose mother potentially was exposed within 2 weeks of delivery.[110] The most current information, including areas with ongoing ZIKV transmission, prevention measures, diagnostic testing recommendations, and guidelines on clinical management are available on the CDC website (http://www.cdc.gov/zika/index.html).

Other Flaviviruses of Medical Importance

Many other flaviviruses can cause sporadic or epidemic illness in humans and may cross-react in serologic tests for the viruses discussed above.[1] St. Louis encephalitis virus (SLEV) and Murray Valley encephalitis virus are mosquito-borne viruses in the same antigenic complex as JEV and WNV. Kyasanur Forest disease virus, louping ill virus, Omsk hemorrhagic fever virus, and Powassan virus are tickborne and genetically related to TBEV. Other flaviviruses reported to cause human illness are Apoi, Bagaza, Banzi, Bussuquara, Dakar bat, Ilheus, Koutango, Langat, Modoc, Ntaya, Rocio, Sepik, Spondweni, Usutu, and Wesselsbron viruses.[1]

Among these other medically important flaviviruses, SLEV and Powassan virus are found in the US. SLEV has been identified throughout much of the US and in parts of Central and South America. SLEV causes sporadic human cases and rare outbreaks, and disease is clinically indistinguishable from WNV disease. SLEV disease incidence has been substantially lower than WNV disease incidence since WNV was first identified in the US in 1999.[111] Powassan virus is endemic in parts of the northeastern and upper midwestern US and in parts of Canada and Russia. From 2003 to 2012, 45 cases of Powassan virus neuroinvasive disease were reported to in the US, but cases in children are rare.[67]

Diagnosis

Flavivirus infections are confirmed most frequently by measurement of virus-specific antibody in serum or CSF. Acute-phase serum specimens should be tested for virus-specific immunoglobulin M (IgM) antibody using an enzyme immunoassay or microsphere immunoassay. With clinical and epidemiologic correlation, a positive IgM test has good diagnostic predictive value, but cross-reaction with related arboviruses from the same family can occur. For most flavivirus infections, IgM is detectable 3 to 8 days after onset of illness and persists for 30 to 90 days, but longer persistence has been documented. Therefore, a positive IgM test result occasionally can reflect a past infection. Serum collected within 10 days of illness onset may not have detectable IgM, and the test should be repeated on a convalescent sample. IgG antibody generally is detectable shortly after IgM and persists for years. Plaque-reduction neutralization tests can be performed to measure virus-specific neutralizing antibodies. A fourfold or greater rise in virus-specific neutralizing antibodies between acute and convalescent phase serum specimens collected 2 to 3 weeks apart may be used to confirm recent infection or discriminate between cross-reacting antibodies in primary flavivirus infections. In patients who have been immunized or infected with another arbovirus from the same virus family in the past (i.e., who have secondary flavivirus infections), cross-reactive antibodies in both the IgM and neutralization assays may make it difficult to identify which flavivirus is causing the patient's illness.

Laboratory confirmation for patients with suspected DENV infection and disease onset ≤5 days prior can be made by detecting DENV nonstructural protein 1 antigen by immunoassay or DENV RNA by reverse transcriptase polymerase chain reaction; later in the illness, an IgM enzyme immunoassay can be used.[112] Diagnosis of all flavivirus infections can be made by nucleic acid amplification tests for RNA and viral culture on acute phase serum, CSF, or tissue specimens; however, YFV, DENV, and ZIKV are more likely to be detected using culture or nucleic acid amplification tests than are the neurotropic flaviviruses. Immunohistochemical staining can detect specific viral antigen in fixed tissue.

Antibody testing for common flavivirus diseases is performed in most state public health and many commercial laboratories. Confirmatory neutralizing antibodies, viral culture, nucleic acid amplification testing, immunohistochemical staining, and testing for less common flaviviruses are performed only at the CDC and selected other reference laboratories.

Prevention

Flaviviral infection can be prevented by avoiding exposure to the arthropods that transmit these viruses. Personal protective strategies include wearing repellent, staying in screened or air-conditioned dwellings, and avoiding outdoor activities during times when the vectors are most avidly seeking blood meals. The times of peak feeding vary between vectors; for example, *Aedes aegypti*, the principal vector of YFV in urban areas, DENV, and ZIKV, feeds primarily during the day. The *Culex* spp. vectors of WNV and JEV typically feed from dusk to dawn. Thus sleeping under insecticide-impregnated bed nets may help reduce the risk for JE but not the risk for dengue.[24,113] Wearing light-colored clothing and checking one's body for ticks and removing them promptly may decrease the risk for TBEV and other tickborne infections. Programs to decrease abundance of vector mosquitoes are important to reduce risk but may be difficult to implement and maintain. Effective vaccines are available for prevention of yellow fever, JE, and TBE; vaccines against dengue and WNV disease are under development.

Key Points

Epidemiology, Clinical Features, Diagnosis, Management, and Prevention of Flavirus Infections

Epidemiology

- More than 40 arthropod-borne flaviviruses described, but those most important in causing human illness are yellow fever, dengue, Japanese encephalitis, West Nile, tickborne encephalitis, and Zika viruses

- Transmitted to humans primarily through the bites of arthropods

- Worldwide distribution, but different flaviviruses found in specific geographical regions

Clinical Features

- Most infections asymptomatic

- Symptomatic illness usually manifests as one of three primary clinical syndromes: generalized febrile illness, neurologic disease, or hemorrhagic fever

Diagnosis

- Confirmed most frequently by measurement of virus-specific antibody in serum or cerebrospinal fluid, but cross-reaction with related flaviviruses can occur

Management

- No specific antiviral therapy available
- Treatment is supportive

Prevention

- Personal protective measures to avoid exposure to the arthropods that transmit these viruses
- Vaccines available for yellow fever, Japanese encephalitis, and tickborne encephalitis viruses

Bunyaviruses

Barbara Knust, Marc Fischer

Description of Pathogen

The family Bunyaviridae contains five genera of viruses, including four that have important human pathogens: *Hantavirus, Nairovirus, Phlebovirus,* and *Orthobunyavirus.*[1] A wide range of clinical syndromes in humans exist among the pathogenic bunyaviruses, with severity of human infections ranging from mild febrile illnesses to illnesses with a high case-fatality rate. Important diseases include hantavirus pulmonary syndrome (HPS; *Hantavirus* genus), hemorrhagic fever with renal syndrome (HFRS; *Hantavirus* genus), Crimean-Congo hemorrhagic fever (CCHF; *Nairovirus* genus), Heartland virus disease (*Phlebovirus* genus), severe fever and thrombocytopenia syndrome (SFTS; *Phlebovirus* genus), Rift Valley fever (RVF; *Phlebovirus* genus), and encephalitis caused by California serogroup viruses (*Orthobunyavirus* genus). Owing to pathogenic potential and human-to-human transmission, CCHF virus is considered a biosafety level 4 agent and hantaviruses and RVF virus are biosafety level 3 agents.[2]

The biology of bunyaviruses, including reservoirs, disease syndromes, and transmission modalities, is diverse. All known pathogenic bunyaviruses have either mammal or arthropod reservoirs. Viruses of the *Nairovirus, Phlebovirus,* and *Orthobunyavirus* genera involve an arthropod vector as part of the long-term ecologic maintenance of the virus, with vector-borne transmission commonly involved in human infection. In contrast, hantaviruses are directly maintained in rodent and insectivore/arvicoline reservoirs without a vector-borne component to the transmission cycle.

Epidemiology

Hantaviruses

A wide diversity of hantavirus species have been discovered around the world (Table 219.1). All have been associated with rodent reservoirs and are distributed according to their reservoir. Viruses that are pathogenic to humans are divided among Old World and New World hantaviruses.

TABLE 219.1

Taxonomy and Epidemiologic Characteristics of Select Bunyaviruses

Genus	Species	Geographic Location	Reservoirs	Infection Route
Hantavirus	Important HPS-associated viruses include Sin Nombre virus and Andes virus; many other species exist	Large portions of North and South America	Rodents	Inhalation of rodent excreta, rodent bite
	Important HFRS-associated viruses include Hantaan virus, Dobrava virus, Saaremaa virus, Seoul virus, Puumala virus; other species exist	Large portions of Europe and Asia	Rodents	Inhalation of rodent excreta, rodent bite
Phlebovirus	Rift Valley fever virus	Central and South Africa, Egypt, Saudi Arabia, Yemen	Mosquitoes, ruminants serve as amplifying hosts	Blood or tissue of infected animals, mosquito bite
	Heartland virus	Midwest and southern United States	Unknown	Likely tick bite
	Severe fever with thrombocytopenia syndrome virus	China, Japan, Korea	Unknown	Likely tick bite, possible nosocomial bloodborne transmission
Nairovirus	Crimean-Congo hemorrhagic fever virus	Africa, eastern Europe,	Maintained between ticks and small	Tick bite, blood or tissue of infected animals;

		Middle East, central Asia	mammals, farm animals can be infected	nosocomial and person-to-person transmission
Orthobunyavirus	La Crosse virus	Eastern United States	Rodents	Mosquito bite
	Jamestown Canyon virus	Widely distributed throughout United States	Deer	Mosquito bite

HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

A wide variety of New World hantaviruses can cause disease in humans. All have rodent reservoirs, and pathogenic viruses are known to exist in the United States, Canada, Panama, and across a large portion of South America.[3] Within the US, most cases are due to Sin Nombre virus infection and occur in the western portion of the country.[4,5] A number of species of hantavirus are associated with HPS across South America.[6,7] The route of infection is typically through inhalation of rodent urine or feces or by bite from an infected rodent. Infections are often associated with cleaning or other activities that result in the aerosolization of infectious material from buildings or structures with rodent contamination.[8–10]

Pathogenic Old World hantaviruses are found across Europe and Asia, with Hantaan and Seoul viruses associated primarily with China, Korea, and far east Russia; Dobrava and Puumala viruses are found in western Russia and Europe.[11–15] The globally distributed Norway Rat (*Rattus norvegicus*) is the reservoir for Seoul virus, and cases of Seoul virus can therefore be found across the world. Domestically acquired cases of HFRS due to Seoul virus have been documented in North America, and serologic evidence suggests the presence of the virus in rodent populations in a number of cities in North and South America.[16–18] As with HPS, hantavirus infections resulting in HFRS occur through inhalation of rodent excreta or by rodent bite.

Rift Valley Fever

RVF is known for explosive outbreaks in animals and people. The causative virus is maintained though transovarian transmission in mosquitoes (most commonly *Aedes* spp.), and infected eggs can remain dormant for many years in dried waterbeds and flood plains, with no evidence of activity. Small numbers of wild ungulates may become infected in this enzootic cycle. Outbreaks typically occur after heavy rains and flooding, where expanded wetland areas lead to increased mosquito breeding, resulting in large numbers of infected mosquitoes from reservoir pools. Domestic ruminants (e.g., cattle, sheep, and goats) become clinically affected, with high fatality and abortions observed due to infections. Evidence of RVF activity in animals often precedes evidence of human infections during outbreaks.[19,20]

Farmers, abattoir workers, and other persons with occupational exposures to animals are at greater risk for developing RVF because infections occur through direct contact with blood or bodily fluids of infected animals, often through slaughtering or handling meat.[21,22] Although less common, humans also can be infected through a mosquito bite. There is no evidence of person-to-person or nosocomial transmission. RVF is endemic across a large portion of Africa, and in recent decades, outbreaks also have occurred in the Middle East (Saudi Arabia and Yemen).[20,23–25] Major outbreaks have recently occurred in Kenya, Tanzania, Sudan (2006–2007), Madagascar (2008–2009), South Africa (2010), and Mauritania (2012).[26–31]

Crimean-Congo Hemorrhagic Fever

CCHF virus is transmitted primarily by *Hyalomma* spp. ticks, which are distributed across much of Europe, Africa, and Asia. Cases or seroprevalence has been documented in central Africa, South Africa, the Middle East, central Asia, and southeastern Europe.[32–34] Although not apparent before 2002, thousands of cases occur each year in Turkey.[35] CCHF virus is maintained through a 2-year transmission cycle in which the tick nymphs feed on small mammals in their first year of life and then molt to adults and feed on livestock (e.g., cattle, sheep, and goats) and humans. Overt symptomatic disease is known to occur only in humans. Human infection results from the bite of an infected tick or by contact with tissues, blood, or milk from infected animals.[36–38] Persons who work closely with livestock are at greater risk for developing CCHF, either through direct contact with the animals or tissues, or from bites of ticks or handling ticks associated with the livestock.

California Serogroup Viruses

Several California serogroup viruses are endemic in the US (i.e., La Crosse, Jamestown Canyon, snowshoe hare, Trivittatus, Keystone, and California encephalitis viruses); however, most human disease is associated with La Crosse virus.[39–42] La Crosse virus is the most common cause of arthropod-borne viral (arboviral) infections of the central nervous system among children in the US.[43–47] On average, 80 to 100 cases of La Crosse virus meningitis or encephalitis are reported annually in the US, with almost 90% of them occurring in children.[43–45] La Crosse virus is transmitted by *Aedes triseriatus*, a tree-hole breeding mosquito; small rodents (e.g., grey squirrels and chipmunks) serve as the primary amplifying hosts.[47–49] The virus is endemic in the eastern half of the US, with the highest numbers of cases in Ohio, West Virginia, North Carolina, and Tennessee.[43–45] Infections peak in the summer months of July to September.[43–45]

Jamestown Canyon virus is another mosquito-borne California serogroup orthobunyavirus that is closely related to La Crosse virus.[39–42,49] *Aedes* and *Ochlerotatus* spp. mosquitoes likely are the primary vectors, and deer appear to be important amplifying hosts.[41,50] Although Jamestown canyon virus is widely distributed throughout temperate North America, reports of human Jamestown canyon virus infection have been rare, in part owing to a lack of available diagnostic testing. From 2000 to 2013, 31 cases of Jamestown Canyon virus disease were identified among residents of 13 US states.[51] Most cases occurred during late spring to early fall, but, in contrast to La Crosse virus, only 15% occurred in children. Sixteen (52%) of the cases were identified in 2013, the first year the Centers for Disease Control and Prevention (CDC) implemented routine Jamestown Canyon virus antibody testing, suggesting the disease has been historically under recognized.

Heartland Virus

Heartland virus is a newly identified phlebovirus that was first isolated from two northwestern Missouri farmers hospitalized with fever, leukopenia, and thrombocytopenia in 2009.[52] Based on the patients' clinical findings and their reported exposures, the virus was suspected to be transmitted by ticks. Heartland virus is found in the Lone Star tick (*Amblyomma americanum*).[53] Six additional cases of Heartland virus disease were identified during 2012–2013; four of those patients were hospitalized, including one with comorbidities who died.[54,55] All patients were men 50 years and older (median, 58 years; range, 50–80 years). Patients had symptom onset during May to September (three cases in May, one in July, and two in September). All of the patients had fever, leukopenia, and thrombocytopenia when first evaluated.

Severe Fever With Thrombocytopenia Syndrome Virus

Severe fever with thrombocytopenia syndrome virus (SFTSV) was identified in China in 2011 from patients presenting with fever, leukopenia, thrombocytopenia, and multiorgan dysfunction.[56] One case series of four pediatric SFTSV cases suggests that the clinical findings in children are less specific (e.g., fever, malaise, and gastrointestinal symptoms) and less severe.[57] Only one patient had thrombocytopenia; there were no hemorrhagic or neurologic manifestations and no deaths.

A reported tick bite in the 2 weeks before illness onset was an independent risk factor for SFTSV disease, and SFTSV or viral RNA has been identified in *Haemaphysalis longicornis* and *Rhipicephalus microplus* ticks.[58–60] Subsequent studies have identified SFTSV-positive ticks and human cases in South Korea and Japan, and the widespread geographical distribution of *H. longicornis* ticks (e.g., China, Korea, Japan, Australia, New Zealand, and Pacific Islands) suggests that SFTSV may have a broader distribution.[61–63] Several cluster investigations have suggested person-to-person transmission of SFTSV through direct contact with blood or bloody secretions.[64–66]

Clinical Manifestations

Hantavirus Pulmonary Syndrome

The incubation of HPS is from 1 to 8 weeks.[67] Cases begin with a prodromal syndrome, with symptoms including fever, myalgia, nausea, vomiting, and diarrhea (Table 219.2). For patients who develop pulmonary symptoms, bilateral noncardiogenic pulmonary edema can develop within a matter of hours, which may radiographically resemble acute respiratory distress syndrome.[4,68–70] Myocardial depression occurs in severe cases of HPS, with death often due to hypoxia and hypovolemia; the case-fatality rate is approximately 35%.[71] Clinically, HPS is similar in children and adults.[72,73] Mild cases of laboratory-confirmed hantavirus infection without pulmonary symptoms have been reported, although it appears to be less frequently observed than HPS.[16]

TABLE 219.2

Clinical Characteristics of Bunyavirus Diseases

Disease	Viruses	Common Symptoms	Treatment
Hantavirus pulmonary syndrome	Important viruses include Sin Nombre virus and Andes virus; many other species exist	Febrile prodrome followed by acute respiratory distress	Supportive; extracorporeal membrane oxygenation as possible salvage therapy
Hemorrhagic fever with renal syndrome	Hantaan virus, Dobrava virus, Saaremaa virus, Seoul virus, Puumala virus; other species exist	Febrile prodrome, possible renal failure, hemorrhage, and shock	Supportive; ribavirin if administered early in disease (patients usually seen late)
Rift Valley fever	Rift Valley fever virus	Febrile illness, possible hemorrhage, hepatitis, meningitis, retinitis	Supportive
Crimean-Congo hemorrhagic fever	Crimean-Congo hemorrhagic fever virus	Febrile prodrome, myalgia, nausea/vomiting, diarrhea, hemorrhage; high case-fatality rate	Supportive: ribavirin if administered early in disease
La Crosse virus disease	La Crosse virus	Commonly asymptomatic or nonspecific febrile illness; possible encephalitis or meningitis	Supportive
Heartland virus disease	Heartland virus	Fever, leukopenia, and thrombocytopenia	Supportive
Severe fever with thrombocytopenia syndrome	Severe fever with thrombocytopenia syndrome virus	Fever, leukopenia, thrombocytopenia, and multiorgan dysfunction	Supportive

Hemorrhagic Fever With Renal Syndrome

The incubation period for HFRS ranges from 7 to 42 days. After clinical disease occurs, it typically progresses through five stages: febrile, hypotensive, oliguric, polyuric, and convalescent (see Table 219.2).[74] Severe manifestations of HFRS include renal insufficiency, shock, and hemorrhage.[11,75,76] Prognosis of HFRS varies, depending on the viral species. The most severe disease is associated with Hantaan and Dobrova/Saaremaa viruses, with case-fatality rates as high as 15%. For Seoul virus disease, the case-fatality rate is about 1%.[11,74,75] Puumala virus, which is endemic to central and northern Europe, causes a similar but less severe form of disease called *neuropathica epidemica,* with an overall case-fatality rate of <0.1%.[77]

Rift Valley Fever

Most human cases of RVF result in mild febrile illness, with myalgias, nausea, and vomiting. A small proportion of cases result in severe disease which can include hemorrhagic symptoms, hepatitis, or encephalitis (see Table 219.2).[21] Hepatitis or retinitis also may develop 1 to 4 weeks after onset of illness.[21,78,79] The overall case-fatality rate for RVF is 1% to 2%.

Crimean-Congo Hemorrhagic Fever

CCHF has an estimated incubation period of 3 to 7 days.[80] The prehemorrhagic stage of the disease is characterized by fever, headaches, dizziness, myalgias, nausea, vomiting, abdominal pain, and diarrhea (see Table 219.2).[36,37] Of the bunyaviruses, CCHF virus has the highest propensity for hemorrhagic manifestations that can include petechiae, epistaxis, hematemesis, melena, gingival bleeding, hematuria, and vaginal bleeding.[32,36,81] Case-fatality rates range from 1% to >50%.

California Serogroup Viruses

Most La Crosse virus infections are asymptomatic or clinically inapparent (see Table 219.2).[41,82–84] The incubation period for symptomatic infections ranges from 5 to 15 days. Clinical findings include fever, headache, vomiting, and fatigue.[41,82–84] Neuroinvasive disease is most common in children and manifests as meningitis or encephalitis.[43–47,83–88] In these cases, cerebrospinal fluid shows a moderately elevated white blood cell count, normal to mildly elevated protein, and normal glucose.[84–88] Computed tomography of the brain is usually normal, whereas electroencephalographic abnormalities are more common and often resemble those seen in cases of herpes simplex virus encephalitis.[41,84,85] Although seizures are common during the acute illness, fatal cases are rare (<1%), and most patients recover completely. However, neurologic sequelae have been reported, including recurrent seizures, hemiparesis, and cognitive and neurobehavioral abnormalities.[84–89]

Of the 31 Jamestown Canyon virus disease cases identified in the US from 2000 to 2013, 17 (54%) presented with meningitis or encephalitis.[51] Fifteen (48%) patients were hospitalized, but there were no deaths. In addition to undifferentiated febrile illness and neuroinvasive disease due to Jamestown Canyon virus infection, previous reports have described a respiratory syndrome with cough, rhinitis, and sore throat.[41]

Laboratory Findings and Diagnosis

Bunyaviruses result in acute infections in humans, with a short period of viremia and no long-term or latent maintenance of the virus. For some diseases (e.g., CCHF, RVF, Heartland virus, SFTSV), direct detection of the virus can be performed by polymerase chain reaction assay, antigen detection, or viral culture during acute stages of disease. However, most bunyavirus infections are confirmed by serology.

Laboratory diagnosis of California serogroup arboviral infections is generally accomplished by testing of serum or cerebrospinal fluid to detect virus-specific immunoglobulin M antibodies.[47] Plaque reduction neutralization tests can be performed to measure virus-specific neutralizing antibodies and to potentially discriminate among cross-reacting antibodies from closely related California serogroup viruses. In fatal cases, nucleic acid amplification, histopathology with immunohistochemistry, and virus culture of autopsy tissues can also be useful. Only a few state laboratories or other specialized laboratories, including those at CDC, are capable of performing this specialized testing.

Treatment

Ribavirin is not efficacious in the treatment of HPS, and no other specific antiviral therapies are available.[90,91] Some studies suggest the utility of extracardiopulmonary oxygenation as a salvage therapy in the management of HPS.[92,93] Data suggest efficacy of ribavirin in improving the course of HFRS (due to Hantaan virus), when administered early in clinical disease.[94] The efficacy of ribavirin in the treatment of CCHF remains controversial. Some data suggest efficacy if administered as postexposure prophylaxis, as well as possible improved disease prognosis if administered early in the disease.[95] Treatment for RVF, La Crosse virus and other California serogroup viruses, Heartland virus, and SFTSV is supportive.

Prevention

Although veterinary vaccines are available for RVF, no human vaccines are licensed and widely available for any of the bunyaviruses, with the exception of hantavirus vaccines available in Korea and China.[96,97] In North America, there is no evidence of person-to-person or nosocomial transmission of hantaviruses, whereas person-to-person transmission of Andes virus in Argentina and Chile has been documented,[98–100] and thus contact precautions are advised when caring for suspected cases in endemic areas. Person-to-person, particularly nosocomial, transmission of CCHF and SFTSV has been documented.[64–66,101,102] Transmission is most probable after contact with blood or body fluids of infected individuals; standard contact precautions are recommended for handling CCHF and STSFV disease cases. Prevention of La Crosse virus and other California serogroup viruses relies on personal protection and vector control measures to reduce the risk for mosquito bites. Because Heartland virus and SFTSV likely are transmitted through infected ticks, prevention depends on using insect repellents, wearing long sleeves and pants, avoiding bushy and wooded areas, and performing tick checks after spending time outdoors.

Hepatitis C Virus

Melissa G. Collier, Deborah Holtzman, Scott D. Holmberg

In the 1970s, after development of routine diagnostic testing for hepatitis A and hepatitis B viruses, a small proportion of acute viral hepatitis could not be attributed to these or other known pathogens. The search for the major etiologic agent of "non-A, non-B hepatitis" culminated in 1989 with discovery of hepatitis C virus (HCV).[1] Although substantially more prevalent among the adult population, HCV infection does occur in children and should be considered a potential diagnosis when relevant clinical or epidemiologic factors are present.

Pathogen

HCV is an enveloped single-stranded RNA virus, of approximately 9500 nucleotides, belonging to the *Hepacivirus* genus in the Flaviviridae family. There are at least six genotypes of HCV, numbered 1 through 7, the nucleic acid sequences of which differ by >30%.[2] More than 50 subtypes that differ by 20% to 25% also have been described. The most common subtypes are 1a, 1b, 2a, and 2b.[3] The prevalence of the genotypes varies by continent and region of the world. Genotype 1 is most prevalent worldwide, comprising 46% of all HCV cases globally and accounting for >75% of cases in the United States; genotype 3 is the next most prevalent worldwide with 30% of cases; genotype 4 is prevalent in Africa and the Middle East, especially Egypt; genotype 5 is prevalent in southern Africa; and genotype 6 is the least prevalent genotype worldwide and is found in a few Southeast Asian countries.[3] Genotype 7 recently was discovered as a new lineage distinct from genotypes 1 to 6 and originated in the Democratic Republic of Congo.[2]

Data on environmental survival, disinfection, sterilization, and decontamination procedures for HCV are limited. Techniques to culture HCV have been developed[4] but are difficult to perform and not always reliable. The inability to culture HCV easily has limited many research efforts, including development of vaccines. One study suggests that HCV in dried plasma can cause infection in experimental animals when left at room temperature for at least 16 hours but not after 4 days.[5] A more recent study suggests that an HCV reporter virus still can infect human tissue cultures after remaining at room temperature for up to 6 weeks.[6] Use of chemical germicides that are capable of producing at least an intermediate level of disinfection activity (e.g., 0.1% glutaraldehyde or 500 ppm free chlorine from sodium hypochlorite – 2 tablespoons of household bleach in 1 gallon of water) or conventional sterilization processing such as steam autoclaving is thought to be suitable for inactivating HCV.[7]

Pathogenesis and Immunity

The primary site of hepatitis C viral replication is the hepatocyte. In the acute phase, histopathologic findings in the liver are typical of acute viral hepatitis and include ballooning degeneration, focal necrosis, and hepatocellular apoptosis.[8,9] These findings are believed to be due to the immune response to virus-infected cells rather than to a direct cytopathic effect of the virus.

The high rate of chronicity with HCV infection in adults is partly attributable to failure of the virus to elicit effective neutralizing antibody. High rates of mutation in the single-stranded RNA genome of HCV are believed to play a role in the pathogen's ability to evade the immune system. In an infected person, several closely related but genetically distinct strains of HCV, termed *quasispecies,* generally occur.[10] Typically, one dominant variant accounts for the majority of circulating virus at any given time. Over time, this variant often loses dominance and is replaced by a new dominant variant.[11,12] Presumably, evolution of quasispecies is a result of the immune response to the dominant variant, resulting in sequential selection of resistant mutants. In addition, sequential infection with different genotypes has been observed in humans.[13,14] Mechanisms associated with persistence and clearance of HCV are not well understood and likely involve both host and viral factors. The heterogeneity of HCV prevents development of conventional vaccines, allows the virus to escape eradication by the host's immune system, and affects the completeness of the response to antiviral therapies with interferon (IFN).[15]

Epidemiology

Prevalence and Incidence

In the United States, the National Health and Nutrition Examination Survey (NHANES) conducted during 2003–2010 found that 1.3% of the noninstitutionalized population older than 6 years were anti-HCV positive, and 1% were HCV RNA positive.[16] Prevalence estimates among children 6 to 19 years of age from NHANES 2003–2010 could not be calculated because so few HCV infections were identified in this age group; therefore it is presumed to be very rare.[16] The prevalence of HCV infection among adolescents with risk factors for HCV infection, such as injection drug use, has been shown to be higher than in the general pediatric population.[17] In a survey of newly incarcerated adolescent detainees, 2% had evidence of HCV infection, 95% of whom reported injection drug use.[18] In a survey of homeless adolescents, of whom one third were injection drug users, the prevalence of HCV infection was 4.4%.[19]

The incidence of HCV infection in the US reached a peak in the 1980s, with approximately 250,000 infections per year, but fell rapidly during the early 1990s. In 2012, an estimated 21,870 new infections occurred.[20] If the incidence remains relatively low, the prevalence of HCV infection among women of childbearing age without behavioral risk factors such as intravenous drug use will continue to decline, and the prevalence among children and adolescents should decline as well.

Transmission

HCV is transmitted most efficiently through direct percutaneous exposure to blood. Mucous membrane exposures to blood also can result in HCV transmission, but this route is less efficient. Although HCV can be detected in saliva, semen, human milk, and other body fluids of some infected persons, these body fluids are not believed to be efficient vehicles of transmission.[21] HCV does not penetrate intact skin spontaneously, and airborne transmission does not occur.[22]

In pediatric practice, perinatal infection currently accounts for most cases of HCV infection, although older children and adolescents can be at risk for HCV infection from injection drug use, sexual transmission, or acquisition from blood, blood products, or solid organ transplants.

Perinatal Transmission and Risk Factors

Among HCV-infected infants and young children in developed countries, perinatal exposure is the most common source of infection. The rate of vertical transmission of HCV is estimated to be 5%, with rates varying between 0% and 25%.[23–26] Most infected infants do not have a positive RNA test during the first month after birth, suggesting that infection occurs at the time of delivery rather than in utero. By 3 months of age, 90% of infected infants test positive for HCV RNA, and by 6 months of age, almost all test positive.[24,27–30] Because maternal antibody can remain detectable in uninfected infants for more than a year, anti-HCV testing is not recommended before 18 months of age.[31]

HCV Viremia.

Perinatal transmission is almost always limited to women with detectable HCV RNA.[25,29,30,32–34] The level of viremia has been shown to be a determinant of perinatal transmission in some studies. For example, women with viral loads $<10^5$ copies/mL were less likely to transmit HCV, even if they were coinfected with HIV.[33–38] However, other studies have failed to demonstrate this association.[24,29,39]

Maternal HIV Coinfection.

The risk for transmission of HCV is 2- to 7-fold higher in infants born to mothers coinfected with HCV and HIV compared with children born to mothers infected with HCV alone.[24,40–42] Higher HCV RNA levels among HIV-coinfected women may explain in part the increased risk for vertical transmission. HIV infection also was shown to facilitate entry and replication of HCV in blood cells which might increase the risk for perinatal transmission.[43,44] In addition, compared with infants who do not become infected with HIV, infants of coinfected mothers who develop HIV infection have a higher risk for developing HCV infection.[38]

Prolonged Rupture of Membranes.

Rupture of membranes ≥6 hours before delivery has been associated with higher rates of transmission in several studies.[24,27,33,45]

Obstetric Procedures.

Data remain limited on the role of obstetric procedures in promoting HCV transmission. Internal fetal monitoring was shown to be associated with transmission of infection.[24,46] One study linked amniocentesis to HCV transmission in infants[47]; however, another study showed that only 6% of women who underwent amniocentesis during the fourth month of pregnancy had HCV in their amniotic fluid.[48]

Sex of the Infant.

A few studies have indicated that the rate of perinatal transmission of HCV infection is twofold higher in females compared with males, suggesting that hormonal or genetic factors may influence susceptibility or response to infection.[33,49]

Factors Not Associated With Perinatal Transmission

Mode of Delivery.

Based on well-controlled cohort studies, the mode of delivery (vaginal versus cesarean) does not appear to affect risk for transmission.[25,29,39,45,50,51]

Breastfeeding.

More than 20 prospective cohort studies have not shown any increased risk for HCV infection among breastfed infants compared with formula-fed infants despite 2 years of follow-up after delivery.[23,25,28,29,33,39,45,46,50,51–62] Only one prospective study showed potential perinatal transmission of HCV through breastfeeding. In this study, all three women who transmitted the infection to their babies developed symptomatic liver disease during the transmission period and had high HCV RNA titers in serum.[63]

Other Modes of Transmission and Risk Factors

Injection Drug Use.

HCV is spread efficiently through sharing of materials used to inject drugs. Several studies have demonstrated that, in addition to sharing of needles and syringes, sharing of paraphernalia used to inject drugs (e.g., water for rinsing needles and syringes or dissolving drugs, "spoons" or "cookers" used for preparing drugs, and "cottons" used to filter the drug solution as it is drawn into the syringe) also plays an important role in transmitting HCV.[64–66] In the US, injection drug use accounts for about 75% of acute HCV infections among persons 30 years or younger.[17] Historically, approximately 80% of injection drug users became infected within the first 2 years of beginning to inject, with >90% infected within 5 years.[66] The incidence of HCV infection among injection drug users in the past decade may be lower, but is still in the range of 15% to 20% per year.[67] As a consequence, people who have ever injected drugs, even if only briefly, may have been infected with HCV and should be screened for evidence of infection (Box 220.1).

Box 220.1

Recommendations for Hepatitis C Virus Testing

Test Routinely on the Basis of Risk

Persons who ever injected illegal drugs, including those who injected once or only a few times many years ago

Persons with selected medical conditions, including:

- Persons who received clotting factor concentrates produced before 1987

- Persons who ever received long-term hemodialysis
- Persons with persistently abnormal serum alanine aminotransferase levels

Prior recipients of transfusions or organ transplants, including:

- Persons who were notified that they received blood from a donor who later tested positive for hepatitis C virus (HCV) infection
- Persons who received a transfusion of blood or blood components before July 1992
- Persons who received an organ transplant before July 1992

All persons born between 1945 and 1965

Test Routinely on the Basis of a Recognized Exposure

Healthcare, emergency medical, and public safety personnel after needlesticks, sharps, or mucosal exposures to HCV-positive blood

Children born to HCV-positive women:

- Testing of infants for anti-HCV should be performed no sooner than 18 months of age.
- If earlier diagnosis of HCV infection is desired, reverse transcriptase polymerase chain reaction testing for HCV RNA can be performed at 1–2

months of age and repeated at 6 months of age.

Routine Testing Is Not Recommended (Unless Risk Factors or Exposures as Above)

Healthcare, emergency medical, and public safety workers

Pregnant women

Household (nonsexual) contacts of HCV-positive persons

The general population

Routine Testing Is of Uncertain Need

Settings not confirmed as risk factor or in which prevalence of infection unknown:

- Recipients of transplanted tissue (e.g., corneal, musculoskeletal, skin, ova, sperm)
- Users of intranasal cocaine and other noninjecting illegal drugs
- Persons with a history of tattooing or body piercing

Settings confirmed as risk factor but in which prevalence of infection low:

- Persons with a history of multiple sex partners or sexually transmitted infections
- Long-term steady sex partners of HCV-positive persons

Testing Request by Any Person

Anyone who wishes to know or is concerned regarding their HCV infection status should be provided the opportunity for counseling, testing, and appropriate follow-up.

Sexual Contact.

Sexual contact is not an efficient mode for transmission of HCV infection.[68] Based on available data, there is no increased risk for transmission of HCV among heterosexual couples in monogamous relationships. However, the risk is almost double among people having multiple sexual partners (although this association may be confounded by increased likelihood of injection drug use with increased number of partners) or among those already having a sexually transmitted infection. In addition, the risk for HCV infection through sexual contact increases fourfold among HIV-infected men and women.[68]

Household Contact.

Although rare, transmission among nonsexual household contacts also can occur. The presumed mechanism of transmission is direct or inapparent percutaneous or permucosal exposure to infectious blood or body fluids containing blood.[69] In one documented episode, an HCV-infected mother transmitted HCV to her hemophiliac child during performance of home infusion therapy, presumably when she sustained an unintentional needlestick injury and subsequently used the contaminated needle in the child.[70]

Healthcare Settings.

HCV can be spread through exposures in the healthcare setting. Some body fluids, including cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, and amniotic fluid, are considered potentially infectious. Feces, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered potentially infectious unless they contain blood. Transmission between patients in the healthcare setting generally is associated with inadequate infection prevention practices, such as reuse of needles and syringes and other failures of aseptic technique, contamination of multidose vials, or inadequate cleaning of equipment.[71–75]

There are no formal screening recommendations for people who may have undergone injections or medical procedures in settings with inadequate infection prevention practices. Nonetheless, clinicians should be aware that infection control procedures in many parts of the world are poor and that patients may have been exposed to HCV through unsafe injection practices and failure to follow appropriate aseptic techniques during provision of medical care.

Transfusion of Blood and Blood Products.

Transfusion-acquired HCV infection probably accounted for most HCV infections in children in the 1970s and 1980s, particularly among children undergoing cancer chemotherapy or open-heart surgery.[76–78] A preliminary survey of cancer survivors who received blood transfusions at St. Jude Children's Research Hospital from 1961 to 1992 found 7% to be infected with HCV.[79] Prevalence was highest (11%) in children who received transfusions before 1986. Since 1992, when second-generation HCV enzyme immunoassay (EIA) screening was implemented, the risk for HCV infection from a single transfusion was considered to be <1 per 100,000 units.[79] Nucleic acid testing (NAT) of all donors for HCV RNA, implemented in 1999, has reduced this risk even further to 1 per ≥2 million blood units.[80]

Plasma-derived products such as clotting factor concentrates frequently were contaminated with HCV until 1987, when manufacturers incorporated effective viral inactivation steps into their purification processes.[81] Consequently, people with hemophilia who were treated with factors XIII and IX manufactured before 1987 have a high prevalence of HCV infection.[82] Since December 1994, all immunoglobulin products (intravenous and intramuscular) commercially available in the US must undergo an inactivation procedure or be confirmed as not containing HCV RNA before release.

Organs and Tissues.

Organ and tissue donors are routinely tested for HCV NAT, and transmission through this route is rare. In the past when anti-HCV testing was used instead of NAT, it was possible for a donor to have been infected recently enough to have not seroconverted by the time the organs were procured.[83] Transmission of HCV from an infected deceased tissue donor to a pediatric recipient through use of a cardiopulmonary patch has occurred.[84]

Clinical Manifestations and Natural History

Infants with vertically acquired HCV infection do not usually become icteric or symptomatic, and a substantial proportion have normal or only mildly elevated serum alanine aminotransferase (ALT) levels.[34,49,85] In the 20% to 30% of acutely infected older children and adults who are symptomatic, symptoms usually are mild and indistinguishable from symptoms of other acute viral hepatitides, including jaundice, nausea, anorexia, and right upper-quadrant abdominal pain.[86] Fulminant hepatitis C has been reported, including cases in an infant and a child, but is rare.[87]

The natural history of HCV infection in children differs slightly between perinatally acquired and transfusion-acquired infections (Fig. 220.1). Although the long-term progression of liver disease in HCV infection acquired in infancy and childhood is not well understood, longitudinal studies conducted to date indicate a milder progression of HCV infection in children compared with adults. Infections acquired in infancy are more likely to resolve spontaneously than infections acquired during adulthood. About 20% of perinatally infected children clear the virus during the first 2 years of life, and up to 55% of children with posttransfusion-acquired HCV clear the virus.[49,78,88,89] Most children with chronic infection are symptom free, and hepatomegaly is observed in only 10%. However, fatigue, particularly in teens and young adults, is associated commonly with persistent HCV infection.

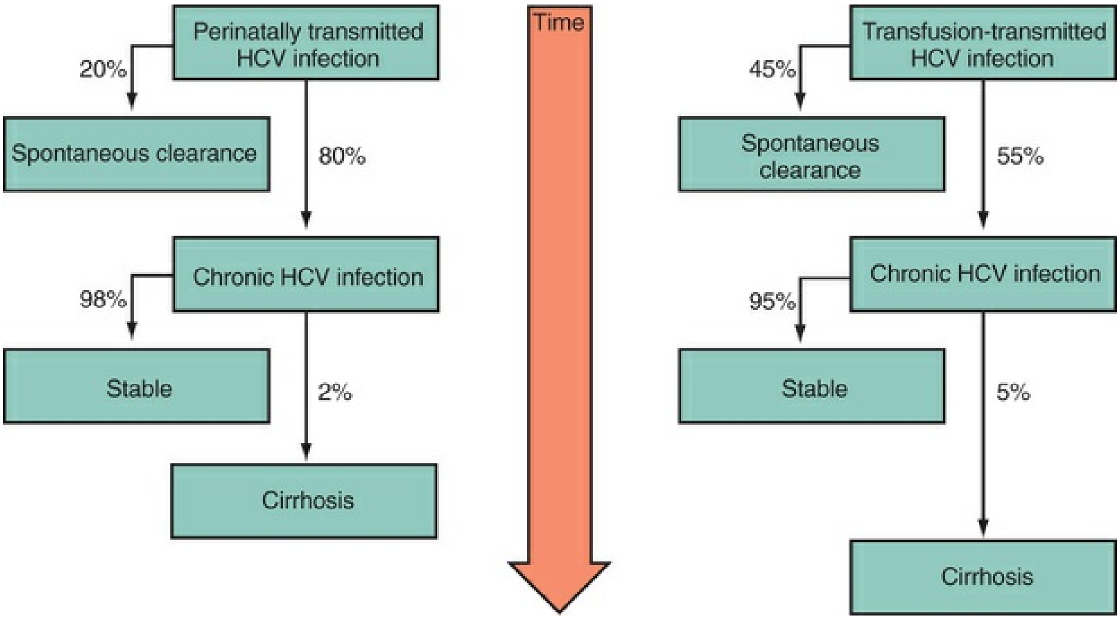

FIGURE 220.1 Natural history of hepatitis C virus (HCV) infection in children.

During chronic infection, about 23% of children have normal serum ALT levels, whereas 25% have consistently high serum ALT levels.[88,90,91] Progression to fibrosis increases with age, and development of advanced liver disease in children is uncommon until >20 years have elapsed since infection. Patients with anorexia, weight loss, abdominal pain, hepatomegaly, and splenomegaly are likely to have advanced liver disease. A study in a quaternary referral center showed that 7 (8%) of 91 children with other comorbid medical conditions developed cirrhosis at a mean age of 12 years. Four of the 7 required transplantation, all of whom had recurrent HCV infection after transplantation and 2 of whom died.[92] The authors recommended treatment to clear the infection before transplantation in order to achieve better prognosis. In another study, 5 (4%) of 121 infected children had bridging fibrosis, and 2 had cirrhosis. Children with fibrosis were older and more likely to have higher serum ALT levels and inflammation on biopsy, suggesting that likelihood of fibrosis increases with time.[93] In another series of 332 HCV-infected children with persistent viremia, 6 (2%) children progressed to decompensated cirrhosis with a mean duration of 10 years (±6 years) between HCV exposure and diagnosis of cirrhosis.[49] Children with genotype 1 are more likely to progress to advanced disease compared with those with genotype 3. Vertically infected children develop cirrhosis earlier than transfused children with no underlying systemic disease. In a study of 67 adolescents and young adults (mean age, 20 years) who tested positive for anti-HCV and had received blood transfusions as infants or young children, 45% of participants cleared the infection, and only three had histologic evidence of progressive liver damage, two of whom also had congestive heart failure.[78] The median time to develop end-stage liver disease among 392 patients with posttransfusion HCV infection was 33 years for those infected between the ages of 21 and 30 years, and only 4% of patients infected before 20 years of age had cirrhosis.[94]

Progression of HCV infection and development of severe liver disease is accelerated in the presence of comorbid conditions such as thalassemia, iron overload, childhood cancer, and HIV coinfection. Children who received blood transfusions for thalassemia are at risk for liver injury from hemochromatosis and after HCV infection have higher risk for progression to cirrhosis.[95–97] A nationwide survey of complications of thalassemia major in North America revealed cirrhosis rates to be 4%, 10%, and 15% for people 0–15, 16–24, and 25 years or older, respectively.[98] Iron overload also may diminish the response to treatment for HCV infection.[99] Children with hemophilia have higher risk for morbidity and mortality due to HCV infection, although end-stage liver disease is uncommon before adulthood.[100] Among children with leukemia, advanced liver disease did not develop during 13 to 27 years of follow-up.[101] In a study of the natural history of HCV among children with inherited bleeding disorders, cirrhosis developed in 75% of children with HIV coinfection, and death was reported in one child also coinfected with HIV.[89]

Hepatocellular carcinoma has been reported rarely among HCV-infected children. A retrospective survey of survivors of childhood cancer from a single medical center who had received blood transfusions before donor screening identified two HCV-infected patients who developed cirrhosis and died of hepatocellular carcinoma approximately 25 years after they were likely to have been infected.[102]

A number of extrahepatic conditions associated with HCV infection in adults, including cryoglobulinemia, glomerulonephritis, and porphyria cutanea tarda, are not common in children.

Data from people infected with HCV at a young age indicate that one third or more apparently resolve their infections. Among the other two thirds, chronic liver disease appears to progress slowly, and serious sequelae are rare during the first 2 decades after infection. The slower progression of HCV in childhood probably is related to the reduced frequency of comorbid factors such as alcohol consumption, hemochromatosis, and nonalcoholic fatty liver disease compared with adults.

Screening and Diagnostic Testing

Screening

Healthcare professionals should ascertain the risk for HCV infection in all patients, including pregnant women and adolescents. In addition, any person with persistent, unexplained elevations in serum ALT level, regardless of risk factors, should be tested for HCV. Furthermore, because people with HCV infection might be reluctant to disclose certain risk factors, any person concerned about his or her infection status should be given appropriate counseling and testing.[31]

Infants of women known to be HCV infected should be screened for HCV RNA on two occasions between the ages of 2 and 6 months or be tested for anti-HCV after 18 months of age. HCV testing should be offered routinely to people most likely to be infected with the virus (see Box 220.1). Routine HCV testing is not recommended for household contacts of HCV-positive persons unless a history exists of a direct percutaneous or mucosal exposure to blood. Identification of people at risk for HCV infection provides an opportunity for testing to determine their infection status, medical evaluation to determine their disease status if infected, and antiviral therapy if appropriate. It also provides the infected person an opportunity to obtain information about how to prevent further liver damage and prevent transmitting infection to others (Box 220.2).

Box 220.2

Key Counseling Messages for Persons Who Test Positive for Hepatitis C Virus Infection

To Protect the Liver From Further Harm, Hepatitis C

Virus (HCV)-Positive Persons Should:

Not start any new medicines, including over-the-counter and herbal medicines, without checking with their physician

Be vaccinated against hepatitis A and B

Avoid drinking alcohol

HCV-Positive Persons Should Be Advised:

HCV is *not* spread by sneezing, hugging, coughing, food or water, sharing eating utensils or drinking glasses, or casual contact.

HCV-positive persons should *not* be excluded from work, school, play, childcare, or other settings on the basis of their HCV infection status.

To cover cuts and sores on the skin to keep from spreading infectious blood or secretions

Not to share toothbrushes, dental appliances, razors, or other personal-care articles that might have blood on them with other people

To discuss the risk for transmitting HCV with their sexual partners. Although risk for transmission is low, they may decide to use barrier precautions (e.g., latex condoms).

For HCV-Positive Women Considering Pregnancy or Who Have Had Children:

No evidence exists that mode of delivery (vaginal versus cesarean) is related to transmission; therefore, determining the need for cesarean delivery versus vaginal delivery should not be made on the basis of maternal HCV infection status.

Data indicate that breastfeeding does not transmit HCV, although HCV-positive mothers should not breastfeed if their nipples are cracked or bleeding.

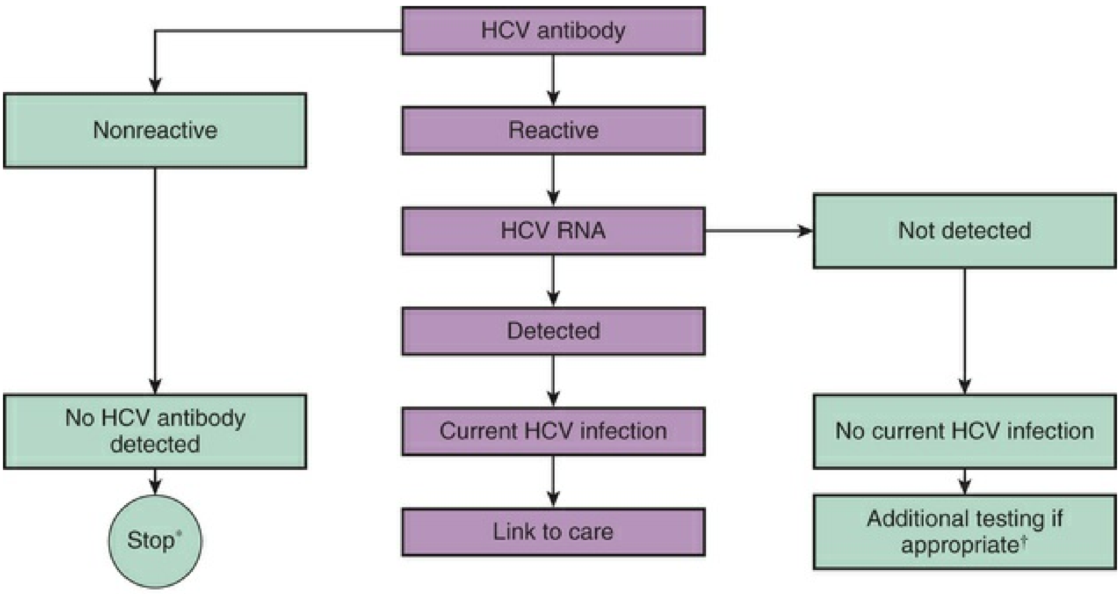
HCV-Positive Persons Should Be Evaluated for Presence or Development of Chronic Liver Disease, Including:

Assessment for biochemical evidence of chronic liver disease

Assessment for severity of disease and possible treatment according to current practice guidelines in consultation with, or by referral to, a specialist knowledgeable in this area

The incubation period for HCV infection averages 6 to 7 weeks, with a range of 2 weeks to 6 months. The time from exposure to development of viremia is usually 1 to 2 weeks. Because HCV infection is asymptomatic in most cases, diagnostic testing in the pediatric age group is recommended in the following circumstances: (1) infants born to HCV-infected women and infants born to mothers with risk factors for HCV infection, such as history of injection drug use; and (2) adolescents with risk factors for HCV infection, including history of drug use and multiple sexual partners.[31] Although HCV is not efficiently transmitted through sexual contact, adolescents with multiple sexual partners are more likely to engage in other high-risk behaviors, notably drug use.[103]

Box 220.1 summarizes the recommendations for HCV testing. A suggested testing algorithm for people with suspected HCV infection is provided in Fig. 220.2.



* Testing for HCV RNA or follow-up testing for HCV antibody is recommended for person exposed to HCV within the past 6 months.

† Past, resolved infections can be distinguished from false-positive anti-HCV testing results by testing with another anti-HCV assay. Repeat HCV RNA testing if HCV exposure occurred within the past 6 months or if clinical disease is present and specimen storage or handling was suspect.

FIGURE 220.2 Testing algorithm for identifying active hepatitis C virus (HCV) infection. (Adapted from Centers for Disease Control and Prevention. Testing for HCV infection: an update of guidance for clinicians and laboratorians. MMWR Morb Mortal Wkly Rep 2013,62:362−365.)

Diagnostic Testing

The goal of HCV testing is to identify persons currently infected with the virus. All persons requiring HCV screening should first be tested for anti-HCV antibodies using a US Food and Drug Administration (FDA)-approved assay and, if positive, tested for HCV RNA. Anti-HCV testing includes both laboratory-based assays and a point-of-care assay.[104] The current EIAs for anti-HCV antibodies are 97% sensitive and >99% specific, but antibody testing cannot distinguish between acute, chronic, and resolved infections. The recombinant immunoblot assay (RIBA) was used in the past to confirm HCV infection; however, this assay is no longer available.[105] In the absence of RIBA, positive anti-HCV antibody tests should be followed by HCV reverse transcriptase polymerase chain reaction to detect HCV RNA in blood. Quantitative or qualitative NAT tests approved by the FDA with detection levels of ≤25 IU/mL should be used. True-positive anti-HCV test results can be distinguished from false-positive anti-HCV test results in the case of resolved infections by including a second HCV antibody FDA-approved assay that is different from the initial assay (see Fig. 220.2).[105]

Infants who are infected perinatally should not be tested for anti-HCV antibodies before 18 months of age because passively acquired maternal antibodies might be detected up until 18 months. The presence of HCV RNA in the mother and infant is the most reliable means of detecting perinatal transmission of HCV. Infants born to HCV-positive mothers can be tested for HCV RNA on two occasions between the ages of 2 and 6 months to detect perinatal transmission because seroconversion occurs on average 8 to 9 weeks after infection and can be delayed up to 6 months after exposure.[106] A small percentage of people with symptomatic acute HCV infection have negative antibody test results at the onset of symptoms; thus serologic testing too early in the course of the infection may not detect and cannot rule out HCV as the cause of acute hepatitis. Also, by the same logic, persons who are immunocompromised should be tested using HCV RNA.

Among people infected with HCV, genotyping is recommended for guiding the duration of therapy and predicting the response to treatment regimens. Currently, treatment of HCV genotypes 1 and 4 using IFN and ribavirin requires twice as long (48 weeks) as treatment of genotypes 2 and 3 (24 weeks). Infection due to the latter genotypes also are much more likely to be treated successfully with IFN and ribavirin. This may change with licensure in children of new all-oral direct-acting antiviral therapy.

Management of Hepatitis C Virus Infection

There are no specific recommendations for management of HCV infection in children and adolescents, and most management strategies are derived from adult studies. However, in view of the long duration of infection among children and adolescents compared with adults, regular follow-up for chronic HCV infection is necessary.

Monitoring Serum Aminotransferase Levels

Normal serum ALT levels are not reliable indicators for lack of hepatic inflammation; however, elevated serum ALT levels are suggestive of hepatic inflammation. Therefore serial measurement of serum ALT can be used to monitor disease activity. HCV-infected children can be followed regularly by physical examination and measurement of serum ALT level every 6 to 12 months.[107] More frequent follow-up is needed in children suffering from comorbidities such as HIV coinfection, thalassemia, or malignancy.

Evaluation of Liver Damage

Liver biopsy can provide important information about the amount and pattern of scar tissue in the liver to guide monitoring and treatment. Liver specimens are evaluated for the grade and stage of disease using the Metavir fibrosis score (F0–F4) and Ishak fibrosis score (0–6).[108] Although liver biopsy often is viewed as a gold standard, the accuracy of liver biopsy is affected by sampling and interpretation errors. Also, there is a small risk for complications associated with the procedure. Obtaining an adequate number of biopsy samples of appropriate size and using standard grading and staging criteria improve diagnostic accuracy. Noninvasive methods to monitor stage of liver disease have become popular in recent years, using combinations of routine blood tests (aspartate aminotransferase, ALT, albumin, bilirubin, international normalized ratio, and complete blood count), serum fibrosis marker panels, liver imaging (ultrasound or computed tomography), and transient elastography.[109,110] These methods are reliable in identifying cirrhosis and in excluding fibrosis, but they are less accurate in identifying patients with moderate levels of fibrosis.

For clinicians, the liver biopsy is most frequently used to determine whether to proceed with therapy, but this invasive procedure currently is being supplanted at many medical centers by elastography (Fibrotest) or noninvasive serum biomarkers (FIB-4 or APRI scores). However, because new all-oral therapies for adults have become highly efficacious for all genotypes and stages of liver fibrosis or cirrhosis—with >90% cure rates after 12 weeks or less—some adult clinicians no longer perform liver biopsy.

Children and young adults with genotype 2 or 3 HCV infection are more responsive to IFN-based treatment.[111,112] However, progression to cirrhosis and hepatocellular carcinoma is highly unlikely in children. Because of this, deferring treatment until the child reaches adulthood or until direct-acting antiviral therapies are available in children is a valid approach and should be considered. Patients to consider treating with IFN and ribavirin before direct-acting antiviral regimens are available include patients with comorbid medical conditions (i.e., requiring immunosuppressive therapy) that would necessitate prompt treatment or signs of severe or rapidly progressive liver dysfunction, confirmed by liver biopsy. Patients with cirrhosis or a coexisting malignancy can be followed by annual measurement of serum α-fetoprotein level and a liver ultrasonography.[112]

For children and young adults with HCV infection, decisions regarding treatment can be based on genotype and patient age.[111,112]

Treatment

Treatment aims to prevent complications and death from HCV infection. Several virologic measures are used to document response to treatment. The most important is sustained virologic response (SVR), which is defined as the absence of HCV RNA for ≥12 weeks after discontinuation of therapy. Most patients who achieve an SVR show definitive absence of viremia and normal liver function.[111]

Acute Infection

Several studies of adult patients have examined the effectiveness of antiviral agents during the early phase of infection and suggest higher SVR rates among people acutely infected compared with response rates observed among people with chronic HCV infection.[113–115] Currently, there is no consensus on the type or duration of therapy required or the timing of initiation of therapy. Only one study reported treatment of acute HCV infection (genotype 4) in a pediatric patient with pegylated IFNα-2b (PEG-IFNα-2b), and the child achieved SVR.[116] Treatment of acute HCV infection is a rapidly evolving area of research, and more specific guidelines for treatment of acute HCV infection in children are likely to be forthcoming. The American Association for the Study of

Liver Diseases, the Infectious Diseases Society of America, and the International Antiviral Society—USA jointly prepared a document providing guidelines for testing, management, and treatment of hepatitis C in adults on their website.[117]

Chronic Infection

HCV is the only chronic viral infection that can be cured (i.e., achievement of SVR). This is a rapidly evolving field because new oral direct-acting antiviral agents (e.g., sofosbuvir, simeprevir, and ledipasvir) are making therapy all-oral, of shorter duration (8–12 weeks), without side effects, and highly curative. The decision to treat chronic HCV infection traditionally has depended on assessing the patient's age and severity of disease and the efficacy of the chosen therapy and its adverse events as well as the patient's adherence to treatment and willingness to complete the regimen. The very high cost of the new direct-acting antiviral agents must be considered because many public and private insurance programs are limiting access to these drugs to patients with advanced fibrosis or cirrhosis. Because of rapid evolution of options and practices, treating clinicians should consult the latest American Association for the Study of Liver Disease/Infectious Diseases Society of America guidelines.[117] IFN-based regimens are the only chronic HCV treatments approved by the FDA for children.

Because of the possibility of spontaneous clearance of the virus among children <3 years of age, as well as the adverse effects of current medications, which include spastic diplegia, treatment of children in this age group has not been approved.[111,118] In 2008, the FDA approved the use of PEG-IFNα-2b in combination with ribavirin for treatment of children 3 years and older. In 2011, the FDA approved the use of PEG-IFNα-2a with ribavirin in children 5 years and older. The Key Points box summarizes the currently approved FDA treatment regimens for chronic hepatitis C in children and adolescents. Before treatment initiation, it is necessary to know the viral genotype because this will affect the response to therapy. Higher SVR rates are achieved for infections due to genotypes 2 and 3 compared with genotypes 1 (the most common genotype in the US and Europe) and 4.[107,111,112,119] The durations of therapy are 24 weeks for genotypes 2 and 3 and 48 weeks for genotypes 1 and 4.

Combination treatment with PEG-IFNα-2b and ribavirin achieved the best SVR rates in all genotypes in the pediatric age group.[119] Large trials that included more than 100 children 3 years and older showed SVR rates ranging from 44% to 53% for genotype 1 and 80% to 100% for genotypes 2 and 3.[120–122] PEG-IFNα-2b should be discontinued temporarily if the neutrophil count falls below 750 to 1000 cells/mm^3 and should be resumed when the count increases.[119] Compared with regular IFNα-2b, PEG-IFNα-2b is more convenient because of the once-weekly administration and limited duration of influenza-like symptoms.[120–124] Ribavirin in combination with PEG-IFNα-2b enhances the second and third phases of viral decay, which reduces the probability of relapse.[125]

The most common adverse events associated with IFN are influenza-like symptoms, particularly fever, headache, fatigue, and irritability, which are almost universal after the first few doses but usually resolve in children by the second or third week of therapy.[121,123,126] Weight loss also is common, but a compensatory catch-up weight gain occurs after completion of treatment.[121–123] In addition, a temporary decrease in height growth occurs during therapy, which resolves after discontinuation.[121–123] Bone marrow suppression is the most severe adverse event and can lead to neutropenia or thrombocytopenia, but it can be managed by reduction of the IFN dosage.[121–123,126,127] With therapy, mood disturbances and suicidal ideation are common, and more so among adolescents and those with preexisting mood disorders.[119] Depression occurred in 13% of participants in one study.[126] Abnormalities of thyroid function also can occur, but these normalize after completion of treatment.[120,121,126] Hemolysis is a common adverse effect of ribavirin and can require discontinuation of the drug. Teratogenicity is a major concern for men as well as women, who should avoid conception during therapy and for 6 months thereafter. Treatment with IFN is contraindicated in patients with certain comorbid conditions such as depression, psychiatric conditions, seizures, renal insufficiency, and autoimmune hepatitis.[119]

Special attention is needed for children with anemia and thalassemia. Erythropoietin and darbepoetin might be used to decrease the hemolytic effect of ribavirin therapy in patients with preexisting anemia. However, the effect of erythropoietin on SVR is unknown.[128] Children with thalassemia may require more transfusions and chelation therapy as a result of hemolysis due to ribavirin therapy and iron overload.[128,129]

In summary, the efficacy of combined therapy in children reflected by SVR rates of 50% and 90% in genotype 1 and genotypes 2 and 3, respectively, warrants its use. However, longitudinal studies are needed to investigate adverse events after completion of therapy, such as thyroid function abnormalities and growth alterations.

Future Treatments

Therapy for hepatitis C is a rapidly evolving field with numerous drugs under development. Highly effective direct-acting antiviral agents have been approved by the FDA for the treatment of chronic HCV, are currently on the market, and promise to change the landscape of HCV therapy. This includes three different drug combinations: sofosbuvir (polymerase inhibitor) with ledipasvir (NS5A inhibitor); simeprevir (NS3/4A inhibitor) with sofosbuvir; and the four drugs ombitasvir (NS5A inhibitor), paritaprevir (NS3/4A serine protease inhibitor), dasabuvir (nonnucleoside NS5B polymerase inhibitor), and ritonavir (CYP3A4 inhibitor).[130–132] All of these drug combinations were well tolerated and achieved high SVR (>95%) after 12 weeks of therapy. Unfortunately, no safety and efficacy trials for these drugs have been completed yet in pediatric patients.

Prevention

Comprehensive recommendations for prevention and control of HCV infection have been published.[31] For example, immunoglobulin has not been shown to be effective for postexposure prophylaxis of hepatitis C, and its use is not recommended.[31] There is no recommendation to screen women for HCV infection either before or during pregnancy, unless they have risk factors for HCV infection. Currently, both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists support breastfeeding in HCV-infected women.

However, HCV-infected women should abstain from breastfeeding if their nipples are cracked or bleeding. Box 220.2 provides key counseling messages for persons with HCV infection. Regardless of risk factors, all children should be immunized against hepatitis A and B.[133,134] Development of a vaccine for hepatitis C has been challenging given the genetic heterogeneity of HCV, the high mutation rate, and the lack of a cell culture system. However, novel vaccine candidates based on molecular technology are being explored.[135,136]

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of Hepatitis C Virus Infection

Epidemiology

- Incubation period: 2 weeks to 6 months
- At least 6 genotypes: genotype 1 most common in the US and Europe
- Prevalence in the US:
  - 0.2% among people aged 6 through 11 years
  - 0.4% among people aged 12 through 19 years
- Perinatal transmission accounts for most cases of HCV infection in children.
  - Estimated rate of vertical transmission of 5%

Clinical Features

- Usually asymptomatic in children
  - Only 20% to 30% with mild symptoms indistinguishable from other acute viral hepatitides

- Estimated rates of virus clearance:

- 20% for perinatally infected children

- Up to 55% for children with transfusion-acquired HCV

- Children with genotype 1 compared with other genotypes are more likely to progress to advanced disease.

Diagnosis

- Anti-HCV testing by EIA is the initial serologic assay to detect infection; confirmed by NAT or retest using a second FDA-approved EIA platform (see Fig. 220.2).

- Infants of women known to be infected with HCV should be screened for HCV RNA on two occasions between 2 and 6 months of age and/or be tested for anti-HCV after 18 months of age.

Treatment

- PEG-IFNα-2b SC: 60 μg/m^2/week

- PEG-IFNα-2a SC: 180 μg/1.73 m^2/week

- IFNα-2b SC: 3 million U/m^2 SC 3 times per week for children <61 kg, and 3 million U 3 times per week SC for children ≥61 kg

- Ribavirin: dose is dependent on the type of interferon being used in combination with ribavirin and the weight of the child

EIA, enzyme immunoassay; FDA, US Food and Drug Administration; HCV, hepatitis C virus; IFN, interferon; NAT, nucleic acid testing; PEG, pegylated; SC, subcutaneous; PO, oral.

Rubella Virus

Yvonne A. Maldonado, Avinash K. Shetty

Rubella (i.e., German measles) is a benign, self-limited, vaccine-preventable viral illness. Acquired rubella is characterized by an exanthem and lymphadenopathy, although infants and children with rubella frequently are asymptomatic. Much of the morbidity attributed to rubella virus (RuV) occurs from in utero transmission, especially during the first trimester, resulting in miscarriage, stillbirth, or congenital rubella syndrome (CRS). Sequelae of CRS include growth retardation, deafness, congenital heart disease, and mental retardation.

Routine childhood vaccination with rubella-containing vaccine (RCV) has resulted in elimination of rubella and CRS in the World Health Organization (WHO) Region of the Americas in 2009.[1] However, rubella and CRS remains a major public health problem in many countries worldwide.[2]

Pathogen, Pathogenesis, and Immune Response

RuV is the only member of the *Rubivirus* genus within the Togavirus family. It is a spherical virus that is 50 to 70 nm in diameter and contains a single-stranded, positive-sense RNA genome.[3] The nucleoprotein core is surrounded by a glycolipid envelope; the lipid component is host cell derived. There is only one antigenic type of RuV.[4] Humans are the only natural hosts of RuV.

RuV contains three major structural proteins: E1, E2, and C. E1 and E2 are glycosylated envelope proteins that make up the spiked 5- to 6-nm surface projections of the viral surface. C is the capsid nucleoprotein. Monoclonal antibodies directed against epitopes of E1 and E2 have neutralizing activity. However, E1 is the primary immunodominant epitope that binds hemagglutination and neutralizing antibodies. E1 plays a major role during virus entry into target cells due to its receptor-binding and membrane-fusion functions.[5] Although no definite cellular receptor has been identified for RuV, the E1 protein can bind to myelin oligodendrocyte glycoprotein (MOG), allowing virus entry into certain target cells.[6] MOG is expressed primarily on human central nervous system (CNS) cells and placenta and may be important in the neuropathogenesis of CRS.[7]

RuV is readily inactivated by chemical agents, lipid solvents, heat (>56°C), cold (−10°C to −20°C), ultraviolet light, and extremes in pH (<6.8 and >8.1). RuV grows well in a variety of primary and continuous cell lines.

Pathogenesis of Acquired Rubella Infection

Rubella is most likely transmitted by direct or aerosol contact with upper respiratory tract secretions of infected people. Infectivity, which correlates with virus shedding from the nasopharynx, can occur 1 week before to 2 weeks after rash onset.[8,9] People are most infectious from 5 days before until 6 days after the onset of rash.[10]

After exposure, the virus attaches to and invades respiratory epithelium and then spreads hematogenously to regional lymphatics. Primary viremia occurs 5 to 7 days after infection. Virus replicates in local and distant reticuloendothelial sites and is followed by secondary viremia at high levels, especially during the second week of infection. Cell-associated virus can be recovered from peripheral blood lymphocytes and monocytes for up to 4 weeks after infection.[11]

Within 8 to 14 days after exposure, active viral replication occurs throughout the body and can be recovered from numerous sites, including the respiratory tract, skin, lymph nodes, urine, cerebrospinal fluid, and breast milk.[12–14] Maximal nasopharyngeal shedding, the development of humoral immunity, and clinical manifestations of infection occur during this period.

Immune Response in Acquired Rubella Infection

Humoral immunity to natural and vaccine RuV is characterized by development of a variety of antibody types reactive to distinct viral antigens, including viral hemagglutinins, complement-fixing (CF) antigens, and precipitating antigens.[15] Development of hemagglutination inhibition and neutralizing antibodies occurs with the onset of the rash illness, and CF antibodies are detected 1 week later. Peak titers of hemagglutination inhibition and neutralizing antibodies occur about 2 weeks after rash onset; CF antibodies peak about 2 weeks later. The hemagglutination inhibition and neutralizing antibodies persist for life.

Although the antibody titers induced by the RA 27/3 vaccine virus currently used in the United States are lower than those induced by natural infection, the nature of the antibody response is similar to the response to natural infection.[16] High-avidity IgG antibodies against the neutralizing epitope of E1 glycoprotein is an important correlate of RuV protection.[17] Vaccine-induced immunity is long lasting, with detectable antibodies for 20 years found in 95% of patients.[18] Rarely, serologically confirmed reinfections can occur after earlier infection or vaccination.[19]

The role of cell-mediated immunity (CMI) in rubella is poorly understood. CMI to RuV develops at least 1 week before the development of humoral immunity and likely persists for life. Transient suppression of CMI and a decrease in numbers of leukocytes (i.e., neutrophils and lymphocytes) can occur after natural infection or vaccination.[3] Clinically significant immunosuppression has not been described in immunocompetent people after acquired rubella infection.

Pathogenesis of Congenital Rubella

In contrast to acquired rubella infection, congenital infection results in a persistent, progressive infection.[8,19] Infants with CRS can shed RuV in nasopharyngeal secretions and urine for up to 1 year and can transmit rubella to susceptible contacts. Placental and fetal infection with RuV occurs most consistently after maternal infection during the first trimester of pregnancy, and early fetal infection, especially during organogenesis, is associated with increased risk of fetal death or teratogenicity.[20,21] Maternal rubella infection in the first trimester of pregnancy results in fetal defects in 85% to 90% of cases; risk drops to 50% with maternal infection at 13 to 16 weeks' gestation and 25% at 15 to 16 weeks.[22,23] Fetal defects are rare if maternal infection occurs after 16 weeks' gestation.[23] However, sensorineural deafness can occur with maternal infection as late as 20 weeks' gestation.[24]

Factors associated with the greater susceptibility of the placenta and fetus to RuV during the first trimester are unknown. Pathologic effects of congenital infection primarily are the result of a generalized virus-induced, progressive, necrotizing vasculitis.[25] Human fetal endothelial cells are highly permissive to RuV.[26] Fetal histopathology is characterized by noninflammatory damage to endothelial cells of small blood vessels resulting in thrombosis and surrounding tissue necrosis.[27] The resulting parenchymal hypoplasia produces characteristic clinical findings associated with CRS.[8]

Other pathologic effects are focal inflammation, edema, and granulomatous changes. Evidence of mitotic arrest through cytoskeletal derangements, apoptosis, and chromosomal defects has been identified in congenitally infected fetuses and in chronically infected human embryonic cells and may represent other pathologic mechanisms leading to reduced cell numbers and hypoplasia.[28,29] The spectrum of fetal infection varies from extensive involvement of multiple organs when infection occurs early in the first trimester to focal involvement of a few organs, especially of the eye and auditory system, which occurs in fetal infections after 11 to 12 weeks' gestation.

Immune Response in Congenital Rubella Infection

Humoral and CMI responses in congenital rubella infection are distinct from those observed after acquired infection (Fig. 221.1). With congenital infection, fetal immunoglobulin (Ig) M antibodies to RuV can be detected as early as 20 weeks' gestation, and fetal IgG can be detected by the middle of the second trimester. Concentrations of IgM and IgG continue to rise throughout the first few months of life. IgM levels decline by about 6 months of age, and IgG levels persist for life.[30]

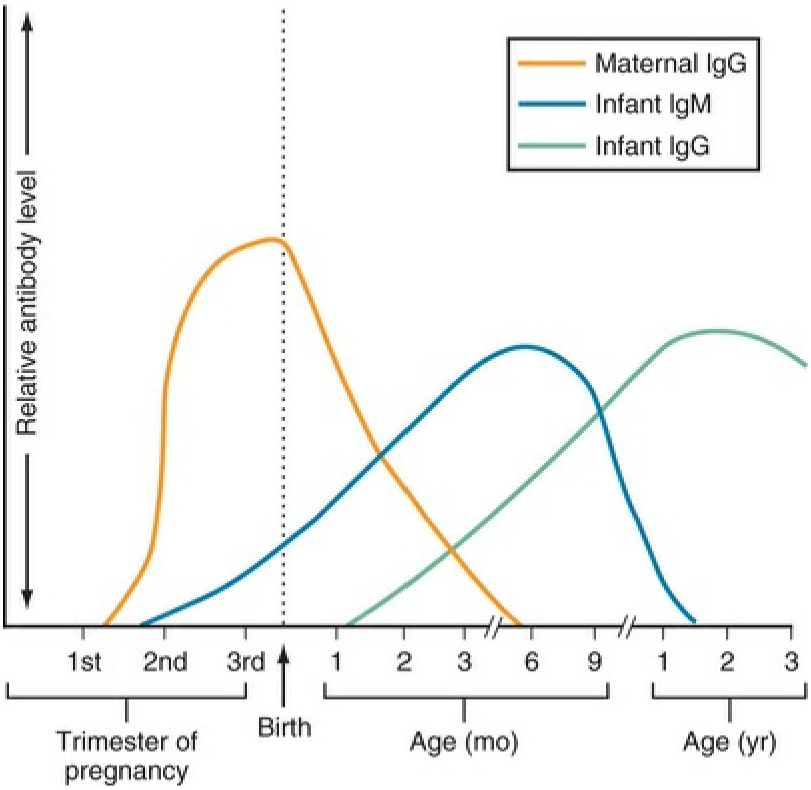

FIGURE 221.1 Immune responses in congenitally acquired rubella after maternal infection in the first trimester of pregnancy. IgG, immunoglobulin G; IgM, immunoglobulin M. (Modified from Best JM, O'Shea S. Rubella virus. In: Lennette EH, Schmidt NJ [eds]. Diagnostic Procedures for Viral, Rickettsial, and Chlamydial Infections, 6th ed. Washington, DC, American Public Health Association, 1989, pp. 731–795.)

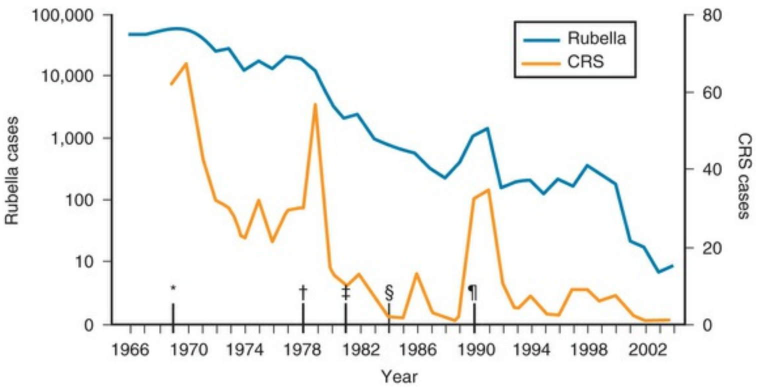
Children with CRS have low-avidity IgG antibodies in contrast with the high-avidity IgG antibodies of their mothers or cases of postnatal infection.[31,32] CMI responses to congenital rubella, including delayed-type hypersensitivity reactions, lymphocyte-mediated cytotoxicity, phytohemagglutinin-induced lymphocyte transformation, and interferon production, are decreased compared with responses after acquired infection. The most depressed CMI responses are observed in infants infected earliest in gestation.[33]

Epidemiology

Rubella infection occurs most often in late winter and early spring. Before the introduction of rubella vaccine in 1969, rubella epidemics occurred in 2- to 4-year cycles; larger epidemics occurred at 6- to 9-year intervals. Young children were most susceptible to rubella infection (highest attack rate, 5–9 years of age).[34] Most adults were not susceptible during cyclic epidemics. Before licensure of rubella vaccine in 1969, 57,600 rubella cases and 62 CRS cases were reported annually in the United States.[35] After vaccine licensure, the incidence of rubella declined dramatically. Since 2001, fewer than 25 rubella cases/year and fewer than 4 CRS cases/year were reported. In 2004, rubella was no longer endemic in the United States (Fig. 221.2).[36]



* 1969 – First official recommendations are published for the use of rubella vaccine. Vaccination is recommended for children 1 year of age to puberty.
† 1978 – Recommendations for vaccination are expanded to include adolescents and certain adults, particularly females. Vaccination is recommended for adolescent or adult females and males in populations in colleges, certain places of employment (e.g., hospitals), and military bases.
‡ 1981 – Recommendations place increased emphasis on vaccination of susceptible people in training and educational settings (e.g., universities, colleges) and military settings, and vaccination of workers in health-care-settings.
§ 1984 – Recommendations are published for vaccination of workers in daycare centers, schools, colleges, companies, government offices, and industrial sites. Providers are encouraged to conduct prenatal testing and postpartum vaccination of susceptible women. Recommendations for vaccination are expanded to include susceptible people who travel abroad.
¶ 1990 – Recommendations include implementation of a new 2-dose schedule for measles-mumps-rubella vaccine.

FIGURE 221.2 Number of reported cases of rubella and congenital rubella syndrome (CRS) by year and chronology of rubella vaccination recommendations by the Advisory Committee on Immunization Practices in the United States, 1966–2004. (Modified from Centers for Disease Control and Prevention. Achievements in public health. Elimination of rubella and congenital rubella syndrome—United States, 1969–2004. MMWR Morb Mortal Wkly Rep 2005;54:279–282.)

In the postvaccination era, young unvaccinated adults were most susceptible to rubella infection. Rubella outbreaks in the mid-1970s and 1980s occurred mostly among unvaccinated adolescents and young adults in college campus and work settings.[37] Between 1989 and1991, rubella outbreaks occurred among unvaccinated people who belonged to religious groups that traditionally refuse vaccination.[38] Rubella attack rates among susceptible people in closed communities (e.g., college dormitories, military facilities) range from 75% to 90%; however, attack rates can approach 100%

among household contacts. In the mid-1990s, reported rubella cases occurred primarily among foreign-born, young Hispanic adults.[39] In recent outbreaks, cases have occurred among people born outside the United States or among underimmunized people.[40]

In 2004, a CDC panel verified rubella elimination in the United States.[41] In the postelimination period from 2004 through 2012, 79 rubella cases and 6 CRS cases (including 3 cases in 2012) were reported in the United States; all cases were known importations or from unknown sources (Fig. 221.3).[40] US rubella immunization programs include two strategies: universal immunization of all infants and targeted vaccination of susceptible prepubertal girls and women of child-bearing age. Success has been achieved primarily with universal childhood immunization. By 1998, more than 90% of 2-year-old US children had received at least one dose of a measles-containing vaccine, usually measles-mumps-rubella (MMR) vaccine.[42]

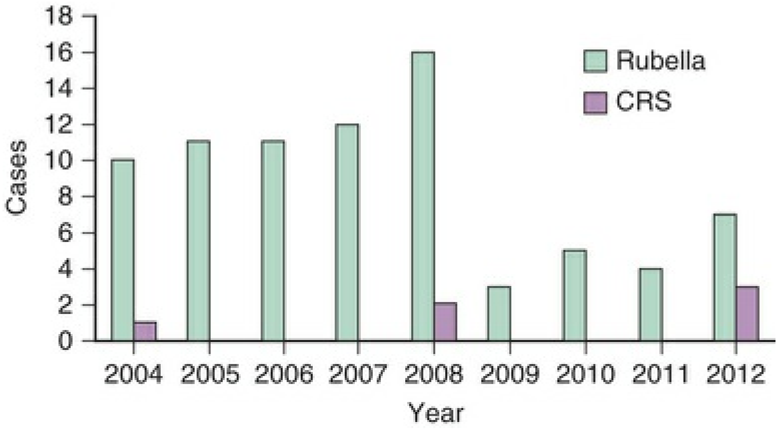


FIGURE 221.3 Number of reported cases of rubella and congenital rubella syndrome (CRS) according to the National Notifiable Diseases Surveillance System, United States, 2004–2012. (From Centers for Disease Control and Prevention. Three cases of congenital rubella syndrome in the postelimination era —Maryland, Alabama, and Illinois, 2012. MMWR Morb Mortal Weekly Rep 2013;62:226–229.)

Based on national serosurveys (1999–2004), rubella seropositivity rates were about 95% among children and adolescents between the ages of 6 and 19 years.[43] However, about 10% of women of childbearing age were rubella seronegative. Women born outside of the United States or from countries lacking rubella vaccination are more likely to be rubella nonimmune, predisposing their infants to CRS.[44]

In 2010, the Pan American Health Organization announced the elimination of rubella and CRS in the WHO Region of the Americas.[45] Although progress has been made in global rubella control, the burden of rubella and CRS remains substantial in low- and middle-income countries.[1,2] Approximately 100,000 infants are born annually with CRS.[2] Partial vaccination strategies have resulted in large rubella outbreaks in Japan, Poland, and Romania.[46–48]

WHO has targeted regional elimination of rubella by 2015 and measles and rubella elimination in five WHO regions by 2020 as part of the Global Vaccine Action Plan.[49] In 2011, the WHO recommended that all countries introduce RCV in their routine immunization programs as part of accelerated measles control and elimination.[50] By 2012, 132 (68%) of 194 WHO member states had included at least one dose of RCV, compared with 99 (51%) in 2000 (Fig. 221.4).[1] During 2000 through 2012, reported rubella cases globally declined by 86% from 670,894 to 94,030.[1] Rubella control and elimination worldwide largely depends on sustained, high-quality immunization programs and robust surveillance systems.[1,2]

during 2013 through 2015. (From Lambert N, Strebel P, Orenstein W, et al. Rubella. Lancet 2015;385[9984]:2297–2307.)

Clinical Manifestations

Acquired Rubella

The incubation period from exposure to onset of exanthem is 14 to 21 days (mean, 18 days). The illness is mild and often subclinical in up to 50% of cases.[44] Nonspecific prodromal symptoms, which occur 1 to 5 days before onset of exanthem, include fever, eye pain, sore throat, arthralgia, and gastrointestinal complaints. Prodrome is rare in infants and young children.

The characteristic clinical findings are rash and suboccipital adenopathy. Rash usually begins on the face, spreads in a cephalocaudal direction to involve the entire body over the next 24 hours, and fades during the ensuing 2 or 3 days, also in a cephalocaudal direction. The median duration of rash is 3 days. Usually erythematous and maculopapular, the exanthem also can be scarlatiniform, morbilliform, or macular. In adolescents, the rash can be confused with acne, whereas in adults, the rash may be pruritic. Other symptoms include low-grade fever and lymphadenopathy. Lymphadenopathy usually occurs with rubella infection and can be detected for up to 1 week before rash onset. The posterior auricular and suboccipital lymph nodes usually are involved, but generalized involvement can occur. Transient polyarthralgia and polyarthritis occur frequently in adults, especially in women.

Reinfection is uncommon. Reinfection that occurs during pregnancy and produces fetal infection is documented but is rare.[51,52] Reinfection usually is subclinical and nonspecific clinically, and the diagnosis is made only by serologic methods.

Congenital Rubella Syndrome

Clinical manifestations of CRS reflect the chronic, progressive nature of the infection.[8,19] Fetal infection can lead to early miscarriage, spontaneous abortion, or stillbirth. Up to 20% of maternal infections occurring up to 8 weeks' gestation result in miscarriage. The association between intrauterine rubella and congenital cataracts was first described in 1941.[53] Congenital defects occur in 85% to 90% of infants infected in the first trimester, and virtually no defects are identified in infants infected after the first 16 weeks' gestation (Fig. 221.5).[22,23] Infants infected in the first trimester are more likely to have multiple congenital defects, whereas those infants infected after 11 to 12 weeks of gestation more likely have only deafness or retinopathy as a clinical manifestation. Clinical manifestations of CRS can be evident at birth or, more commonly, can result in normal-appearing infants who have late-onset sequelae. Early clinical manifestations can be transient or progressive (Table 221.1).[8]

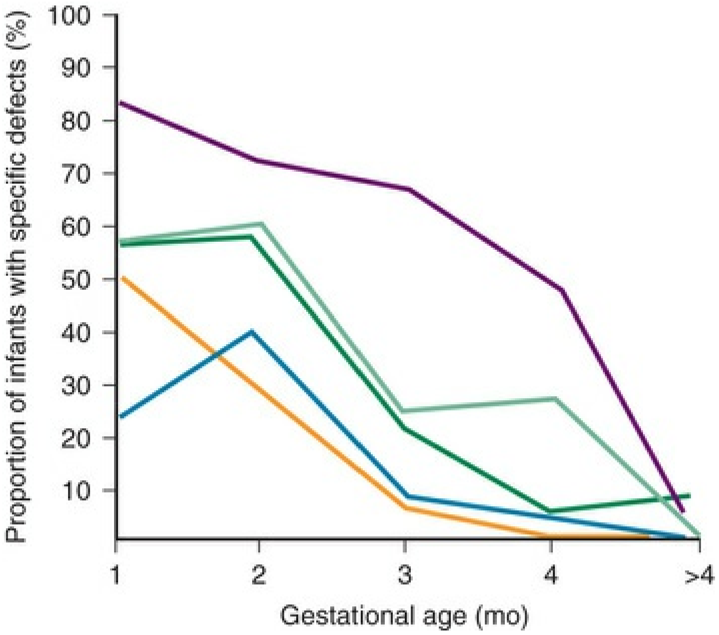

FIGURE 221.5 Time of maternal infection and clinical manifestations of congenital rubella: deafness *(purple)*; central nervous system deficit *(light green)*; heart disease *(dark green)*; cataract or glaucoma *(orange)*; neonatal purpura *(blue)*. (Redrawn from Best JM, O'Shea S. Rubella virus. In: Lennette EH, Schmidt NJ [eds]. Diagnostic procedures for viral, rickettsial, and chlamydial infections, 6th ed. Washington, DC, American Public Health Association, 1989, pp. 731–795.)

TABLE 221.1

Clinical Features Associated With Congenital Rubella Syndrome

Category	**Common**	**Uncommon**
PRESENT AT BIRTH		
Transient	Low birth weight Thrombocytopenic purpura Hepatomegaly Splenomegaly Bone lesions	Cloudy corneas Hepatitis Generalized lymphadenopathy Hemolytic anemia Pneumonitis
Permanent	Sensorineural deafness Peripheral pulmonary stenosis Pulmonary valvular stenosis Patent ductus arteriosus Ventricular septal defect Retinopathy Cataract Microphthalmia Psychomotor retardation Cryptorchidism Inguinal hernia Diabetes mellitus	Severe myopia Thyroid disorders Dermatoglyphic abnormalities Glaucoma Myocardial abnormalities Sensorineural deafness
DELAYED	Peripheral pulmonary artery stenosis Mental retardation Central language defects Diabetes mellitus Immune complex disease Hypogammaglobulinemia	Severe myopia Thyroiditis Hypothyroidism Growth hormone deficiency Chronic rash Pneumonitis Progressive panencephalitis

Modified from Banatvala JE, Best JM. Rubella. In: Brown F, Wilson R (eds). Topley and Wilson's Principles of Bacteriology, Virology, and Immunity, 7th ed, vol 4. London, Edward Arnold, 1984, pp. 271–302.

Transient, early clinical manifestations of CRS reflect acute nonspecific immunologic responses to congenital viral infection. In neonates, manifestations include generalized lymphadenopathy, hepatosplenomegaly, intrauterine growth retardation, hepatitis, jaundice, hemolytic anemia, pneumonitis, meningoencephalitis, cloudy corneas, bony radiolucencies, and diarrhea.[54–57] Thrombocytopenic purpura with petechiae and blueberry muffin lesions, which usually represent focal areas of dermal erythropoiesis, are associated more often with rubella than with other congenital viral infections. Transient manifestations typically resolve within days to weeks, usually without long-term sequelae. More than 50% of newborns with clinically apparent CRS have low birth weight, and persistent postnatal growth retardation.

Permanent or progressive manifestations of CRS can occur in any organ. Organ systems most commonly involved are the heart, eye, brain, and auditory system. Sensorineural deafness is the most common manifestation of CRS. Cardiac anomalies occur in more than 50% of infants born with symptomatic CRS. The most common lesions are patent ductus arteriosus, peripheral pulmonary arterial stenosis, and ventricular septal defects. The most common ocular manifestations are salt-and-pepper retinopathy and cataracts.[58] Retinopathy occurs in 20% to 50% of infants with symptomatic infection and usually is unilateral. Cataracts occur in up to one third of infants with retinopathy, are bilateral in about 50% of affected infants, and are associated with microphthalmia in about 60%.

Late-onset manifestations of CRS may not be identified before 2 years of age or later.[59,60] Findings include endocrinopathies, chronic immunologic defects, auditory and ocular dysfunction, and vascular and CNS disease. The most common endocrinopathy is insulin-dependent diabetes mellitus,[61] occurring at a more than fourfold the rate among otherwise unaffected children with CRS. The highest rate was reported in a series from Australia, in which 20% of young adults with symptomatic CRS had diabetes mellitus.[62] Thyroid disorders (e.g., hyperthyroidism, hypothyroidism, thyroiditis) have been diagnosed in CRS patients.[63,64]

Glaucoma and abnormalities of the cornea and lens also can have a late onset. Retinal neovascularization due to congenital retinal vascular atrophy can result in visual disturbances. Renal vascular stenosis can lead to hypertension.[8]

CNS defects associated with CRS can be present at birth. In some cases, they are transient manifestations with no permanent sequelae; in others, the symptoms are progressive. Some patients first demonstrate CNS manifestations later in life.[65] Permanent neurologic defects include developmental delay, microcephaly, behavioral disorders, and chronic encephalitis. Developmental delay can be the result of intrauterine damage of the CNS, acute and chronic encephalitis in the immediate postnatal period, or progressive effects of generalized failure to thrive. Microcephaly may not be associated with developmental delay if the decrease in head circumference is a result of generalized growth retardation.[66] Psychiatric and behavioral manifestations, such as reactive or neurotic disorders and autism, occur in up to one third of preschool- and school-age children after congenital rubella.[55,65] Late-onset progressive panencephalitis is a rare complication that usually manifests in the second decade of life.[67]

Permanent manifestations of CRS are common and result in long-term sequelae in 80% or more of infected infants. The most common complications are hearing deficits that can progress or can develop after years of normal hearing. The overall incidence of hearing deficits in children with CRS is about 50%, but they may be identified only after 4 to 6 years of age in up to 20% of children. Ophthalmologic defects, which occur in up to 50% of infants with clinically apparent infection at birth, can result in progressive visual disturbances, especially in children with retinopathy in whom progressive macular scarring develops. Cardiac defects may require surgical intervention. Developmental delay and behavioral disorders usually are progressive; the overall prevalence of permanent CNS involvement is about 10% among infants with symptomatic infection at birth. It is important to evaluate auditory and visual acuity in these children because of the possibility that hearing or vision disturbances are the primary cause of learning disorders.[68]

Laboratory Findings and Diagnosis

Acquired Rubella

Laboratory abnormalities during postnatally acquired rubella infection include leukopenia and relative neutropenia. Because the rubella exanthem is nonspecific, infection cannot be diagnosed on the basis of clinical presentation alone. Serologic tests usually are necessary to confirm the diagnosis. A single elevated rubella-specific immunoglobulin (Ig) M antibody level or a fourfold or greater rise in antibody titer between paired sera collected 2 weeks apart or IgG seroconversion indicates recent infection. Interpretation of serologic results must be based on the timing of the serum samples relative to the rash onset because IgM antibodies may be detectable only from 1 or 2 weeks until 3 weeks after onset of rash.[69]

Enzyme immunoassay (EIA) is widely available and often used for detection of rubella-specific IgG and IgM antibodies.[70,71] Latex agglutination, neutralization, and hemagglutination inhibition assays also can be used.[71] False-positive IgM serology results can occur for people with parvovirus B19 infections, heterophile antibodies, or rheumatoid factor.[44] Assays for IgG avidity are helpful to resolve false-positive IgM test results. The avidity assay should be performed at a CDC reference laboratory and can differentiate recent primary rubella infection (i.e., low-avidity IgG) from past infection or reinfection (i.e., high-avidity IgG).[71,72] An EIA antibody level of 10 IU/mL or higher is considered evidence of immunity.[73] Detection of functional neutralizing antibodies by high-throughput immunocolorimetric system may be useful to determine immunity to rubella in vaccinated people.[74]

RuV can be isolated from nasopharyngeal secretions, throat, and urine, but culture is impractical compared with serology. Detection of RuV genome by real-time reverse-transcriptase polymerase chain testing on nasal, throat or urine samples also has been described.[75] Molecular epidemiology and phylogenetic analysis is beneficial to monitor the source of RuV and transmission patterns, document maintenance of rubella elimination, and differentiate wild-type RuV from vaccine strains.[71,76]

The differential diagnosis of rubella infection includes other benign rash illnesses of childhood, such as enteroviral infections, exanthem subitum, adenovirus and Epstein-Barr virus infections, and streptococcal infections. Infection due to *Mycoplasma pneumoniae* and drug rashes also can mimic rubella infection.

Congenital Rubella

A maternal history of rubella during pregnancy or neonatal manifestations suggesting congenital infection, such as microcephaly, hepatosplenomegaly, generalized lymphadenopathy, thrombocytopenia, or ocular abnormalities, should prompt evaluation for CRS. The diagnosis of congenital rubella requires virologic or serologic confirmation. RuV can be isolated for 1 or more years from nasopharynx, the buffy coat of the blood, cerebrospinal fluid, and urine of infants with congenital infection (Table 221.2).[77]

TABLE 221.2

Frequency of Virus Excretion by Age of Infants With Congenitally Acquired Rubella

Age	Number With Positive Culture (%)
0–1 mo	71/85 (84)

1–4 mo	50/81 (62)
5–8 mo	26/80 (33)
9–12 mo	11/98 (11)
13–20 mo	4/115 (3)
3 mo–15 yr	0/20 (0)

Data from Cooper LZ, Krugman S. Clinical manifestations of postnatal and congenital rubella. Arch Ophthalmol 1967;77:434–439.

The serologic confirmation of congenital rubella is difficult. Rubella-specific IgM can be measured in cord blood or neonatal serum but is associated with false-positive reactions in the presence of rheumatoid factor or maternal IgG.[78–80] Serial measurement of IgG may therefore be necessary. Specimens drawn at 3 and 6 months of age should be tested in parallel. Persistence or increasing concentrations of rubella-specific IgG antibodies over several months is diagnostic of congenital infection.[81]

Treatment

No specific therapy is available for congenital or acquired rubella infection. The infant with presumed or proven congenital rubella infection should undergo complete evaluation for associated congenital defects, including ophthalmologic, auditory, cardiac, and neurodevelopmental assessments.

Complications of Acquired Rubella

Arthropathy is the most common complication of acquired rubella, occurring in up to 70% of adults. It is unusual in children.[44] Women are affected more often than men. Clinical manifestations include arthritis and arthralgia of multiple joints; fingers, knees, and wrists are involved most often.

Onset is usually 1 to 6 days after rash onset, and symptoms persist for a mean of 9 days. Arthritis can persist for up to 1 month and rarely relapses occur, but chronic arthritis is rare.[8,44] RuV has been detected in the synovial fluid and synovium in patients with arthritis after postnatal infection or vaccination. The pathogenesis of rubella arthritis likely is immune complex-mediated given the appearance of arthritis with the antibody response.[8]

An association between acquired rubella infection and rheumatoid arthritis has been reported.[82] Higher prevalence of rubella hemagglutination inhibition antibodies has been demonstrated among people with rheumatoid arthritis than matched controls, and RuV and antigens have been detected in the synovial fluid of a few patients with juvenile idiopathic arthritis. A cohort study of more than 3000 women failed to demonstrate an association between rubella vaccination and new-onset chronic arthropathy.[83]

Acute encephalitis occurs in 1 in 6000 cases and usually manifests within 4 days of the onset of rash.[44,84] CSF analysis demonstrates a mild pleocytosis, usually greater than 300/mm^3 (>50% lymphocytes), a normal or slightly elevated protein level, and a normal glucose concentration. The course of rubella encephalitis varies. In most people, illness is mild and self-limited, but deaths have occurred occasionally. Symptoms of peripheral neuritis are commonly reported. Rarely, progressive panencephalitis occurs in patients after acquired rubella.[85] The clinical course is similar to that of subacute sclerosing panencephalitis caused by rubeola virus.

Thrombocytopenia with purpura occurs in 1 of 3000 cases.[86] The prevalence is higher among children than adults, and the condition occurs more often in girls than in boys. Thrombocytopenia usually is self-limited but can last days to months. Rare complications of rubella are myocarditis, pericarditis, follicular conjunctivitis, hemolytic anemia, and hepatitis.

Prevention

Immunization

Rubella vaccination programs in the United States targeted universal immunization of infants to eliminate the CRS in subsequent generations.[87] Selective vaccination of prepubertal women or women of reproductive age also is recommended. The RA 27/3 strain of live, attenuated rubella virus constitutes the rubella vaccine currently licensed in the United States The vaccine strain is grown in WI-38 or MRC-5 human diploid cell cultures, and immunization produces a mild, noncommunicable infection.

In the United States, rubella vaccine is available in combination with mumps and measles (MMR) vaccine or as a quadrivalent vaccine in combination with measles, mumps, and varicella (MMRV). One dose of the vaccine administered at 12 or more months of age is immunogenic in more than 95% of recipients and confers lifelong immunity in more than 90% of vaccinees; the seroconversion rate is 99% after two doses of the MMR vaccine.[44,88–91] Reinfection after vaccination is rare. Polymorphisms in HLA genes (e.g., HLA-DPB1) are associated with interindividual differences in rubella virus–specific humoral immunity after vaccination.[92,93]

The CDC and the American Academy of Pediatrics (AAP) recommend universal rubella-containing vaccination (as part of MMR or MMRV) at 12 to 15 months of age, with a second dose before school entry (4–6 years) or sooner.[94–96] The second dose of vaccine is intended to provide immunity to children who do not seroconvert after the first dose (i.e., primary vaccine failure).

All people who have not received the vaccine at school entry must receive the second dose of MMR or MMRV as soon as possible, optimally before starting junior high or middle school (11–12 years). In two postlicensure studies, one additional febrile seizure per about 2300 to 2600 children between the ages of 12 and 23 months was observed in those who had received MMRV compared with those who received MMR vaccine and varicella vaccine administered as separate injections at the same visit.[97,98] There was no increased risk of febrile seizures when MMRV was administered as the second dose at 4 to 6 years of age.

The CDC and AAP recommend the administration of the MMR and varicella vaccines as two injections at a single visit at 12 through 47 months of age, unless the parent or caregiver expresses a preference for the MMRV vaccine. Use of the MMRV vaccine generally is preferred over separate injections for the second dose of the MMR and varicella vaccines at any age (15 months to 12 years) and for the first dose at 48 months of age or later.[96]

Rubella-containing vaccine is recommended for susceptible nonpregnant women of childbearing age, at-risk postpuberal males and females in colleges, military recruits, recent immigrants, teachers, childcare providers, and healthcare personnel.[94,95,99] People are considered to be susceptible to rubella if they were born in 1957 or later, did not receive at least 1 dose of vaccine, and have no serologic evidence of immunity.[44,95]

Rubella-containing vaccine is safe and well tolerated.[100] Adverse reactions include rash, fever, and lymphadenopathy in up to 15% of vaccine recipients. Joint pains occur in less than 1% of children, but arthritis and arthralgia occur in up to 25% of postpubertal women after vaccination.[44] Arthropathy begins 1 to 3 weeks after vaccination and is transient. Persistent arthropathy is reported but is uncommon. Transient peripheral neuropathy, thrombocytopenia, and CNS manifestations rarely have been described.

Rubella-containing vaccine should not be administered to pregnant women.[95] The risk of congenital rubella infection after vaccination is estimated at 1.3% based on accumulated data from 226 seronegative women who received rubella vaccine inadvertently during the first trimester of pregnancy and demonstrated seroconversion. Two percent of infants of these women had serologically confirmed rubella infection with no clinical manifestations; no infant had congenital defects.[95,100]

Although administration of live-virus vaccine is contraindicated in immunosuppressed children, those with human immunodeficiency virus (HIV) infection should be given MMR vaccine because of the excess risk of morbidity and mortality associated with measles in this population. HIV-infected children without severe immunosuppression should receive MMR vaccine at the standard recommended ages, although primary vaccine failure may be substantial. Persons who have received immune globulin, blood or blood products, or immunosuppressive therapy should not be vaccinated for at least 3 months and longer if a high dose of immune globulin was given intravenously (see Chapter 6).

Passive Immunity

Immune globulin can modify or suppress clinical manifestations of acquired rubella infection in exposed susceptible people, but it does not prevent rubella infection. Absence of clinical infection may not indicate the absence of viremia, and infants with congenital rubella have been born to women who received immune globulin soon after exposure to rubella during pregnancy. Immune globulin therefore is not recommended routinely for postexposure prophylaxis of susceptible pregnant women and should be considered only if termination of the pregnancy will not be considered.

Public Health Measures

Children with acquired rubella should be excluded from school or group childcare until 7 days after the onset of rash. In outbreak situations, children without evidence of immunity must be vaccinated or excluded for 21 days after rash onset in the last case in the outbreak.[95] Infants with congenital rubella should be considered contagious until 1 year of age unless results of two urine and nasopharyngeal cultures obtained 1 month apart in infants older than 3 months of age are negative for RuV.[95] Healthcare, childcare, military personnel, and college students should be screened for rubella immunity. Susceptible people should be immunized to prevent infection with and transmission of the virus.[94,95,99] Routine serologic screening of postpubertal women is not recommended.

Isolation Procedures

In addition to standard precautions, droplet precautions are recommended for hospitalized persons with postnatal rubella for 7 days after the onset of rash. Contact isolation is required for neonates with suspected congenital rubella.

Key Points

Epidemiology, Clinical Features, Diagnosis, and Prevention of Rubella

Epidemiology

- Vaccine-preventable viral disease of childhood
- Affects only humans and has no animal reservoirs
- Postnatal rubella is transmitted by direct or aerosol contact with respiratory secretions of infected people.
- Rubella has been eliminated from the Americas since 2009 after widespread vaccination.

- Rubella and congenital rubella syndrome (CRS) remain an important public health problem worldwide.

Clinical Features

- Postnatal rubella illness usually is mild and often is subclinical.

- Manifestations of CRS include growth retardation, deafness, cataract, congenital heart disease, and mental retardation.

Diagnosis

- Serology (i.e., positive rubella-specific IgM or significant rise in rubella IgG level) or virus RNA detection by real-time polymerase chain reaction (rt-PCR) testing of clinical samples

- Diagnosis of congenital rubella requires virologic or serologic confirmation.

Treatment

- No antiviral therapy is available.

Prevention

- Live, attenuated rubella-containing vaccines (i.e., MMR or MMRV)

- Rubella-containing vaccines are safe and well tolerated.

RNA Viruses: Coronaviridae

OUTLINE

222 Human Coronaviruses

222

Human Coronaviruses

Susan M. Poutanen

Coronaviruses are included in the Coronaviridae family under the order Nidovirales. They are enveloped, nonsegmented, single-stranded, positive-sense RNA viruses named after their corona-like or crown-like surface projections seen on electron microscopy that correspond to large surface spike proteins (Figs. 222.1 and 222.2). They are host specific and can infect humans and a variety of animals.[1]

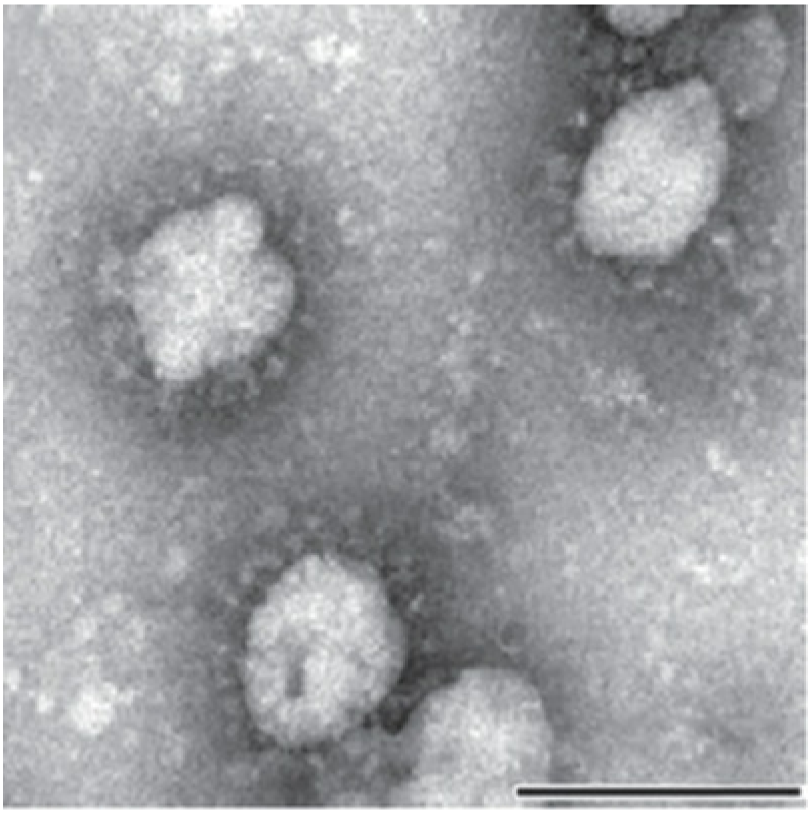

FIGURE 222.1 Negative-contrast electron micrograph of severe acute respiratory syndrome coronaviruses shows the typical crown-like spike proteins on the surface of the coronavirus particles (bar = 100 nm). (From Kuiken T, Fouchier RA, Schutten M, et al. Newly discovered coronavirus as the primary cause of severe acute respiratory syndrome. Lancet 2003;362:263–270.)

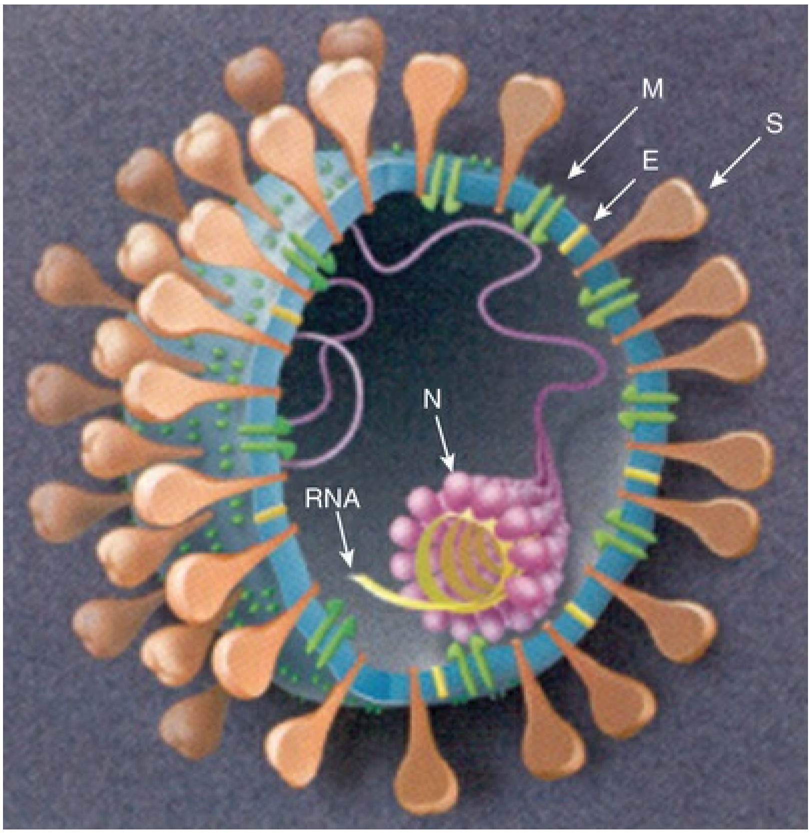

FIGURE 222.2 Organization of the spike (S), membrane (M), and envelope (E) glycoproteins in a typical coronavirus is shown for a typical coronavirus. The RNA is protected by the nucleocapsid proteins (N). (From Holmes KV, Enjuanes L. The SARS coronavirus: a postgenomic era. Science 2003;300:1377–1378.)

Four genera of coronaviruses have been described. Human coronaviruses (HCoVs) are part of the *Alphacoronavirus* and *Betacoronavirus* genera[1,2] (Table 222.1).

TABLE 222.1

Human Coronaviruses

Genus	Species	Acronym	Host	Associated Diseases
Alphacoronavirus	Human CoV-229E	HCoV-229E	Human	Respiratory tract infection
	Human CoV-NL63	HCoV-NL63	Human	Respiratory tract infection
Betacoronavirus				
Subgroup A	Human CoV-OC43[a]	HCoV-OC43	Human	Respiratory tract infection
	Human CoV-HKU1	HCoV-HKU1	Human	Respiratory tract infection and possibly gastroenteritis
Subgroup B	SARS CoV	SARS CoV	Human	Respiratory tract infection

Subgroup C	MERS CoV	MERS CoV	Human	Respiratory tract infection
Subgroup D	No human CoV identified	—	—	—
Deltacoronavirus	No human CoV identified	—	—	—
Gammacoronavirus	No human CoV identified	—	—	—

[a] This species has been abolished according to the International Committee on Taxonomy of Viruses. It is now considered part of the species *betacoronavirus 1*.[1] However, because the name HCoV-OC43 is still commonly used, the species is referred to as HCoV-OC43 in this chapter.

CoV, coronavirus; HCoV, human coronavirus; MERS, Middle East respiratory syndrome; SARS, Severe acute respiratory syndrome.

Epidemiology

In the 1930s, coronaviruses were recognized as animal pathogens.[3] Thirty years later, coronaviruses were identified as human respiratory pathogens. The first recognized HCoV strains included 229E and OC43. Strains such as B814, OC16, OC37, and OC48 also were described but were not characterized further.[4–6] Coronavirus-like particles have been detected in stool, primarily in infants with gastroenteritis and necrotizing enterocolitis, but further characterization has not been completed.[7–9]

In 2003, severe acute respiratory syndrome (SARS) CoV was identified as a novel respiratory pathogen responsible for a global outbreak of SARS. First emerging in 2002 in China, the outbreak lasted 9 months and resulted in 8098 people infected and 774 deaths.[10–14] Data suggest that SARS CoV evolved from SARS CoV–like viruses in horseshoe bats, with civet cats and other wild market animals serving as intermediate hosts.[15–20]

Renewed interest in CoV research let to the discovery of two novel HCoVs 2 years later: NL63 (also known as NL or NH) and HKU1.[21–23] HCoV-NL63 has been detected in human respiratory samples from as early as 1981.[24] It is unclear how HCoV-NL63 and HCoV-HKU1 relate to the HCoV strains originally described in the 1960s (i.e., B814, OC16, OC37, and OC48) or to the enteric coronavirus-like particles detected in stool.[25]

In 2012, the Middle East respiratory syndrome (MERS) CoV (also called hCoV-EMC) was identified as a novel CoV responsible for an epidemic of respiratory illness in the Kingdom of Saudi Arabia.[26,27] Data suggest that MERS CoV likely evolved from bat CoV, with camels acting as intermediate hosts.[28] A total of 1733 cases and 678 deaths were associated with MERS CoV as of May 2016.[29]

HCoV-229E, HCoV-OC43, HCoV-NL63, and HCoV-HKU1 are found worldwide and cause disease predominantly in winter and spring months in temperate climates.[24,30] Seroprevalence data suggest that exposure is common in early childhood.[31,32] SARS CoV has not been identified since 2004, when 4 sporadic community-acquired cases of SARS were identified in China[33] and 13 cases linked to laboratory biosafety practice breaches were identified in Southeast Asia.[34–36] During the 2002–2003 outbreak, most SARS CoV transmission occurred within hospitals from patients with unrecognized illness.[37] MERS CoV cases continue in the Middle East, primarily linked to exposure to camel or camel products or close contact with unrecognized cases in hospitalized patients.[38–40] Household transmission also has occurred.[41] In 2015, a large outbreak of MERS CoV in South Korea, affecting 186 cases and associated with 36 deaths, was traced to an individual who returned from travel in the Middle East.[28,29,42]

Modes of transmission for HCoV other than SARS CoV and MERS CoV have not been well studied. Based on studies of other respiratory viruses, transmission likely occurs primarily by a combination of spread by droplet and direct and indirect contact.[43–45] The possible role of aerosol spread needs further study. Droplet spread and direct contact likely are the most common modes of transmission for SARS CoV, although evidence for spread by indirect contact and aerosol also exists.[46–53] There is no evidence of vertical transmission of SARS CoV.[54,55] Transmission of MERS CoV is thought to occur through droplet, contact, and possibly aerosol routes.[40,41,56]

HCoV-229E and HCoV-OC43 are most likely transmitted during the first few days of illness, when symptoms and respiratory tract viral load are maximal.[57,58] Further study is needed to confirm if this also is the case for HCoV-NL63 and HCoV-HKU1. SARS CoV and MERS CoV are most likely transmitted during the second week of illness, when symptoms and viral load in the respiratory tract peak.[59–62] Supershedding events have been associated with SARS CoV and MERS CoV.[39]

The incubation period for HCoV-229E is 2 to 5 days (median, 3 days).[58,63] Further study is needed to confirm the incubation periods for HCoV-OC43, HCoV-NL63, and HCoV-HKU1. The incubation period for SARS CoV is 2 to 10 days (median, 4 days).[59] The incubation for MERS CoV is 2 to 15 days (median, 5 days).[40]

Pathogenesis and Immunity

The pathogenesis of HCoVs has been best described for HCoV-229E, SARS CoV, and MERS CoV. For SARS CoV, most evidence is from infections in adults because few children were affected by the 2002–2003 outbreak.[64]

Human Coronavirus 229E.

HCoV-229E infections are initiated through inoculation of respiratory tract mucosal surfaces. Nasal mucosal plasma exudation and increased interferon γ (IFNγ) levels in nasal lavage specimens correlate with symptom severity.[65,66] Respiratory tract viral loads peak within the first 3 days after infection and drop off dramatically at 1 week, correlating with development and improvement in symptoms.[57,67] Antibodies can be detected at 1 week, correlating with the drop in viral load, and they reach maximal levels approximately 1 week later and decline thereafter.[68]

Immunity is not complete, and reinfection is common.[68,69] Higher circulating antibody levels, especially levels of specific IgA anti-HCoV, correlate with reduced symptoms and reduced virus shedding on re-exposure.[68,70]

Severe Acute Respiratory Syndrome Coronavirus.

SARS CoV infection is initiated through inoculation of the respiratory tract mucosa using angiotensin-converting enzyme 2 acting as the functional receptor for cell entry.[71] Viremia and replication in the lung and gastrointestinal tract follows.[72,73] Replication at other sites likely occurs given the wide distribution of SARS CoV in tissues examined at autopsy.[74,75]

Peak viral loads in nasopharyngeal specimens are detected during the second week of symptoms.[60,73] A rise in SARS CoV–specific antibodies typically is seen at the same time. Increasing antibody titers and symptomatic improvement during the second and third week are associated with a decrease in SARS CoV viral loads.[60,76] Paradoxically, despite a fall in viral load and a rise in SARS-specific antibodies, clinical deterioration is observed in some patients.[60] The host immune responses likely contribute to clinical deterioration in these patients. Elevated levels of IFNγ, inflammatory cytokines interleukin-1 (IL-1), IL-6, and IL-12; neutrophil chemokine IL-8; monocyte chemoattractant protein 1; and IFNγ-inducible protein-10 have been detected, with levels of IL-6 correlating with severity of disease.[77,78]

Middle East Respiratory Syndrome Coronavirus.

MERS CoV infection most likely is initiated through inoculation of the respiratory tract mucosa mediated by dipeptidyl peptidase 4 (DDP4) (i.e., CD26) acting as the functional receptor.[79,80] Viral loads are highest in lower respiratory tract specimens, but real-time polymerase chain reaction (rt-PCR) evidence of MERS CoV also can be found in the upper respiratory tract, serum, stool, and urine.[62] Autopsy data from a single patient did not show extrapulmonary MERS CoV dissemination, but because DPP4 is widely distributed in different tissues, extrapulmonary dissemination is thought to be possible.[79]

Clinical Manifestations

Human Coronaviruses 229E, OC43, NL63, and HKU1.

HCoVs 229E, OC43, NL63, and HKU1 are commonly associated with the common cold, which is typically characterized by rhinorrhea, nasal congestion, sore throat, sneezing, and cough that may be associated with fever.[22,24,67,81–84] Together, the HCoVs are the second most common cause of the common cold after rhinoviruses.[85,86]

Based on data for HCoV-229E, symptoms typically peak on day 3 or 4 of illness and are self-limited.[67,87] HCoVs also may be associated with acute otitis media or exacerbations of asthma.[24,82,84,88,89] Less frequently, these viruses are associated with lower respiratory tract infections, including bronchiolitis and pneumonia, primarily in infants and immunocompromised children and adults.[23,82,84,90–98]

Compared with other HCoVs, HCoV-NL63 more frequently is associated with croup and is the second most common cause after parainfluenza virus type 1.[99,100] A possible association of HCoV-NL63 with Kawasaki disease was not substantiated.[101,102]

HCoV-HKU1 has been associated with symptoms of gastroenteritis, including vomiting and diarrhea, which typically occur along with respiratory symptoms.[84,89,103] HCoV-HKU1 also appears to be more frequently associated with febrile seizures compared with other HCoVs.[84,89]

Severe Acute Respiratory Syndrome Coronavirus.

SARS CoV is associated with severe symptoms.[104–106] SARS CoV disproportionately affects adults, who typically manifest fever, myalgia, headache, malaise, and chills, followed by a nonproductive cough and dyspnea 3 to 5 days later. Approximately 25% develop watery diarrhea. Respiratory distress progresses and requires intubation and ventilation in 25% of cases. The overall associated mortality rate is approximately 10%, with most deaths occurring in the third week of illness.[105] The case-fatality rate for persons older than 60 years of age approaches 50%.[107]

Typical laboratory abnormalities include lymphopenia and increased serum lactate dehydrogenase (LDH) and creatine kinase levels.[108,109] Most patients have progressive unilateral or bilateral, ill-defined airspace infiltrates on chest imaging.[108,110–112] Pneumothoraces and other signs of barotrauma are common in patients receiving mechanical ventilation.[105]

Infants and children younger than 12 years of age who develop SARS typically have fever, cough, rhinorrhea, and milder symptoms compared with adolescents and adults. Associated lymphopenia is less severe, and radiographic changes are milder and usually resolve more quickly than in adolescents and adults. No infants or children died of SARS CoV infection in the 2002–2003 outbreak.[64,113–116] Adolescents who developed SARS had clinical courses more closely resembling that of adults, including fever, myalgia, headache, and chills, and they were more likely to have dyspnea, hypoxemia, and worsening chest radiographic findings.

Women infected with SARS CoV during pregnancy who survive have an increased risk of spontaneous miscarriage, preterm delivery, and intrauterine growth restriction.[54,55,117] Two neonates born to mothers with SARS in the 2002–2003 outbreak developed gastrointestinal complications (e.g., jejunal perforation, necrotizing enterocolitis with ileal perforation) soon after birth, but neither had clinical evidence of SARS CoV infection.[55] It is unclear whether these findings related to complications of maternal SARS or treatments for SARS, such as ribavirin and corticosteroids, used during pregnancy.

Middle East Respiratory Syndrome Coronavirus.

MERS CoV infection is associated with severe symptoms similar to those seen with SARS CoV, although a spectrum of disease, including asymptomatic infections and mild disease, can occur.[27] Most cases have been identified in male adults with comorbidities. Infected children typically have milder symptoms.[27] Fever, myalgia, and chills are followed a few days later by a nonproductive cough and dyspnea. Approximately 25% of patients also have vomiting, diarrhea, or abdominal pain.[27] Rapid deterioration of oxygenation with progressive unilateral or bilateral airspace infiltrates on chest imaging may follow, requiring mechanical ventilation and often associated with acute renal failure.[118]

Laboratory abnormalities include thrombocytopenia, lymphopenia, and an elevated LDH level.[27] The case-fatality rate is high, estimated at 36%.[28]

Diagnosis

Some laboratories offer comprehensive rt-PCR for respiratory tract specimens, which may include detection of HCoVs 229E, OC43, NL54, and HKU1.[84,119] Public health laboratories offer rt-PCR and antibody testing for SARS CoV and MERS CoV testing.[120,121]

Upper and lower respiratory tract specimens are the most appropriate samples for viral detection when testing is available.[62,73,82,84,122] Stool samples frequently are positive for patients with SARS and have been positive for some with MERS CoV[62] and HCoV-HKU1 infection.[73,89,103,122] Serum samples also may be positive by rt-PCR for patients with SARS CoV and MERS CoV infection.[62] For cases of HCoV-299E and HCoV-OC43 infection, specimens are most likely to be positive during the first few days of illness[57]; whether this also is true for HCoV-NL63 and HCoV-HKU1 needs further study. For SARS CoV infection, serum samples for RT-PCR testing are most likely to be positive in the first week of illness,[72,123] but respiratory and stool specimens may not be positive until the second week of illness, when symptoms and viral loads peak.[60,73] Infants and children with SARS CoV infections are less likely to have positive specimens, consistent with the milder symptoms and presumed correspondingly lower viral loads in children.[113,114] For cases of MERS CoV infection, specimens for rt-PCR should be collected from the lower respiratory and upper respiratory tract along with serum and stool samples.[62,124]

Laboratory guidance for SARS CoV and MERS CoV diagnostic testing is available on the Centers for Disease Control and Prevention (CDC) website.[124,125] Because of the potential for false-positive results and the associated public health implications, testing for SARS CoV in the absence of known person-to-person transmission should be done only in consultation with public health departments and when there is a high degree of clinical suspicion. Similarly, testing for MERS CoV should be done only in consultation with public health officials and in the context of known risk factors for MERS CoV infection.

Treatment

Because of the self-limited nature of infection with HCoV strains 229E, OC43, NL63, and HKU1, few treatment studies have been performed. Care typically is supportive.

SARS CoV infections are more serious. Corticosteroids, type 1 IFN agents, convalescent plasma, ribavirin, and lopinavir or ritonavir have been used to treat SARS.[108,126–129] For many of these agents, anecdotal reports suggest benefit, and in vitro assays and animal models offer supportive data,[108,126–138] with the exception of ribavirin, for which in vitro studies do not support efficacy.[135,139,140]

Since the SARS outbreak, viral entry– and protease-inhibiting agents, RNA-interfering agents, and glycyrrhizin have been tested in vitro and appear promising.[140,141] However, no definitive conclusions can be drawn. If SARS CoV re-emerges, clarification of the effectiveness of these treatments through controlled clinical trials will be needed. For MERS CoV, preliminary data suggest several treatments may be useful, but no definitive recommendations can be made at this time.[142]

Prevention

Practicing good hand and respiratory hygiene is the most useful control measure to curb the spread of all respiratory viruses, including HCoVs.[143,144] Prophylactic intranasal IFNα has reduced the duration and severity of HCoV-229E infection in research settings, but it has not been used clinically.[145,146] A proprietary extract of the roots of North American ginseng (*Panax quinquefolium*) can reduce the number of colds and the severity and duration of cold symptoms in adults when taken daily, presumably due to immune stimulation.[147–150] Efficacy for a decrease in the number of colds specifically due to HCoVs has not been studied.

Healthcare personnel should use a gown, gloves, mask, and eye protection for the duration of illness when caring for children hospitalized with signs and symptoms of a respiratory tract infection.[151] The same precautions, with the replacement of the mask by a respirator if available, and negative-pressure isolation are recommended for patients with SARS CoV infection for the duration of illness or 10 days after resolution of fever, provided respiratory symptoms are absent or improving.[151] The same precautions recommended for SARS CoV are recommended for MERS CoV except the duration of precautions should be decided in conjunction with public health authorities.[152]

Standard disinfectants should be used to clean and disinfect environmental surfaces that are frequently touched by infected persons. This can decrease the potential for indirect transmission of HCoVs by fomites.[153]

The control of the 2002–2003 SARS outbreak is credited to the rapid identification of cases and early implementation of infection control and public health measures, including contact tracing and quarantine. If SARS CoV re-emerges, all measures should be implemented urgently in an attempt to prevent a recurrent worldwide outbreak.[28,154,155]

Transmission of MERS CoV within hospitals and households can be averted with the use of infection control precautions,[55] but preventing the transmission from camels to humans is more challenging given the prevalent use of camels for transport, meat, and milk. Recommendations to reduce the likelihood of transmission include regulation of camel movement, enforcing the use of personal protective precautions while handling camels, and educating the public about the risks of consuming unpasteurized camel milk and urine.[156] Given the challenges of following these recommendations, it is likely that sporadic transmission will continue until an effective MERS CoV vaccine is found.[28,157]

Key Points

Epidemiology, Clinical Manifestations, Diagnosis, and Treatment of Human Coronavirus (HCoV) Infections

Epidemiology

- Human coronaviruses (HCoVs) 229E and OC43 (identified in the 1960s) and NL63 and HKU1 (identified in 2004) are found worldwide. Exposure is common in early childhood; in temperate climates, it primarily causes infections in the winter and spring months.

- Severe acute respiratory syndrome coronavirus (SARS CoV) was identified in 2003 as responsible for the 2002–2003 global outbreak of SARS.

- SARS CoV has not been associated with disease since 2004, and the possibility or probability of a large-scale re-emergence of SARS is unknown.

- Middle East respiratory syndrome coronavirus (MERS CoV) was identified in 2012 as responsible for an epidemic of respiratory illness in the Kingdom of Saudi Arabia. Transmission is ongoing and is primarily limited to countries in the Middle East.

- Risk factors include exposure to camels or camel products or close contact with persons infected with MERS CoV.

- The most common modes of transmission are through droplet and direct and indirect contact.

Clinical Manifestations

- HCoV strains 229E, OC43, NL63, and HKU1 are associated with the common cold, acute otitis media, asthma exacerbations, and less frequently, bronchiolitis and pneumonia.

- HCoV-NL63 is also associated with croup. HCoV-HKU1 is associated with vomiting and diarrhea and frequently with respiratory tract symptoms; it appears to be associated more frequently with febrile seizures compared with other HCoVs.

- SARS CoV causes SARS, with an attendant mortality rate of 10%, which primarily affects adults and adolescents. Children younger than 12 years of age who develop SARS typically have less severe manifestations (i.e., fever, cough, and rhinorrhea).

- MERS CoV is associated with a spectrum of disease, ranging from asymptomatic and mild disease to severe respiratory disease with an associated mortality rate of 36%.

- MERS CoV primarily affects male adults with comorbidities; children with MERS typically have milder symptoms.

Diagnosis

- Upper and lower respiratory tract specimens can be tested by HCoV real-time polymerase chain reaction.

- Stool samples frequently are positive for patients with SARS CoV and have been positive for some patients with MERS CoV and HCoV-HKU1 infection; antibody tests also are available for SARS CoV and MERS CoV infection.

- Serum samples may be positive for patients infected with SARS CoV and MERS CoV.

Treatment

- Infections with HCoV strains 229E, OC43, NL63, and HKU1 require supportive care.

- SARS CoV and MERS CoV infections have no definitive treatment recommendations because of a lack of controlled trials.

Parainfluenza Viruses

Asunción Mejías, Octavio Ramilo

Human parainfluenza viruses (HPIVs) were first identified in humans in the late 1950s.[1] HPIVs were initially described in children with croup, but the use of molecular diagnostic tools has elucidated their causative role in acute respiratory tract infections in patients who are immunocompromised, have chronic conditions, or are elderly.[2–6] In otherwise healthy children, HPIVs commonly cause upper respiratory tract infections (URIs) and also lower respiratory tract infections (LRIs) such as pneumonia, bronchiolitis, and exacerbations of reactive airway disease.[3,7] HPIVs are responsible for 6% to 11% of total hospitalizations of children younger than 5 years of age, highlighting the need for effective vaccines and antiviral therapies.[3,8]

Description of the Pathogen

Microbiology

HPIVs are pleomorphic, enveloped RNA viruses that belong to the Paramyxoviridae family. There are four antigenically distinct types, 1, 2, 3, and 4, with two antigenic subtypes, 4A and 4B.[9,10] Parainfluenza viruses are divided into two genera based on complement fixation and hemagglutinating antigens. Parainfluenza types 1 and 3 belong to the *Respirovirus* genus, and parainfluenza types 2, 4A, and 4B belong to the *Rubulavirus* genus. Parainfluenza virus type 5 causes disease in animals, and its role in humans remains controversial.[11]

Other viruses in this family include mumps, measles, Hendra, and Nipah viruses; New Castle disease virus; respiratory syncytial virus (RSV); and human metapneumovirus (HMPV).The HPIV serotypes and subtypes display substantial serologic cross-reactivity. The single-stranded, negative-sense, nonsegmented RNA genome (−ssRNA) of HPIV contains approximately 15,000 nucleotides that encode six common structural proteins.

The viral envelope is derived from the host cell and is covered with glycoprotein spikes. Two glycoproteins, the hemagglutinin-neuraminidase (HN) and fusion (F) proteins, play a major role in pathogenesis and are the major antigenic targets for neutralizing antibodies.[12] HN is coupled with the activated F protein to permit the virion entry into the cell. Activation of the F protein is mediated by cellular proteases. The specific localization of these proteases may influence specific-member HPIV cellular tropism.

Pathogenesis and Immunity

HPIVs replicate exclusively in cells of the respiratory epithelium, initially infecting epithelial cells of the nose and nasopharynx. Clinically, HPIVs most commonly affect the large airways of the lower respiratory tract, causing croup.[13] Viral tropism for this anatomic location seems to be related to the abundant ciliated epithelial cells.[14] In more severe cases, infection spreads to the distal airways and causes development of bronchiolitis or pneumonia.

The mechanism of airway and parenchymal injury and resulting symptoms probably are a combination of the host immune response and to a lesser extent the direct viral cytopathic effect. Significant viral replication is detected in the upper (i.e., nose) and lower (i.e., lungs) respiratory tract within 24 hours of infection, with peak viral replication occurring between days 2 to 5. Necrosis and occasionally proliferation of the bronchiolar epithelium accompany the destruction of ciliated epithelial cells in children with pneumonia and bronchiolitis.[15] A peribronchiolar infiltrate of lymphocytes, plasma cells, and macrophages appears along with edema and excessive mucus production, and if pneumonia is prominent, the alveoli are filled with fluid.[16]

Innate Immune Responses, Cytokines, and Chemokines.

By mechanisms that are not completely understood, HPIV-3 modifies the survival and functional properties of human antigen-presenting cells (i.e., monocytes and dendritic cells), which may prevent the development of efficient antiviral responses.[17] HPIVs induce the production of cytokines and chemokines in animal models, under in vitro conditions and in children with acute infections.[18,19] The magnitude of the cytokine response probably is related to the clinical syndrome and virus type.

Local production of interferon γ (IFNγ) was detected in 30% of children with HPIV lower respiratory tract disease, and nasal wash concentrations of interleukin-8 (IL-8) were significantly higher in children infected with HPIV-3 or HPV-1 compared with other HPIV types and in those with lower rather than upper respiratory tract infection.[19,20] A disruption in the mechanism that regulates metalloproteinases (MMPs) also has been associated with increased disease severity in infants with bronchiolitis caused by HPIVs or RSV.[21]

Cellular Immunity.

Host defense against HPIVs is mediated largely by humoral immunity and T-cell recognition of epitopes on the HN and F surface glycoproteins of the virus.[22] Animal models of acute HPIV infection suggest that CD8$^+$ T-lymphocyte–mediated immune responses are critical for viral clearance.[23] Infants with HPIV-induced croup have defective regulation of cell-mediated immune responses compared with children with uncomplicated URIs.[24] This and the prolonged viral shedding and severe disease manifestations observed in people with defective cell-mediated immunity indicate the important role of T lymphocytes in controlling infection.[5,25,26]

Humoral Immunity.

Mucosal immunity appears to play a key role in controlling disease. Studies of adults after an experimental challenge with HPIV-1 and HPIV-2 indicate that neutralizing antibody concentrations in secretions correlate better with protection than serum antibody concentrations.[27,28] In children, secretory antibodies appear 7 to 10 days after the onset of symptoms and peak at about 2 weeks after disease onset.[29] Most children are born with neutralizing antibodies to all four HPIV types, but titers fall sharply during the first 6 months of life.

Most HPIV antibody responses involve serum immunoglobulin G1 (IgG1), but levels of serum IgG3, IgG4, IgA, and IgM rise significantly in 30% of adults. Antigenic variations in HPIV viruses are related to the heterogeneity within the viruses rather than to antigenic viral drift. Reinfections, which occur many times throughout life, most likely reflect waning immunity. After several infections, antibodies may develop that cross-neutralize different parainfluenza virus strains (e.g., HPIV-1 and -3, HPIV-2 and -4).

In immunocompetent people, reinfections are more likely to cause only upper respiratory tract symptoms.[30] In epidemiologic studies, HPIV-3 was isolated from 143 children (i.e., 50% of all HPIV isolates) younger than 5 years of age. Of those, 9% had subsequent reinfections with isolation of the same virus type less than 1 month after the initial infection. Although reinfections are thought to induce increased resistance to LRIs by the infecting serotype, protection appears not to be based entirely on increased humoral immunity.[30,31] In these studies, the clinical manifestations of the reinfection episodes were not different from those of the initial episode. No reinfections were seen with HPIV-1 or HPIV-2.[7]

Epidemiology

The different serotypes of HPIV have distinct epidemiologic patterns that depend on the geographic location. However, overall HPIV seasonal patterns are predictable and cyclic except for tropical countries, where HPIVs do not exhibit seasonal variation.[32,33]

HPIV-1 causes the largest, most defined outbreaks of croup in the fall of odd-numbered years. Outbreaks of HPIV-2, although more erratic and milder, usually follow HPIV-1 outbreaks.[16] A major increase in the number of cases of croup in the autumn usually indicates an HPIV-1 or -2 outbreak.[34] HPIV-3 is the most frequently recovered strain. It is endemic, and infection most commonly occurs during the spring and summer and extends into autumn, especially when other HPIV outbreaks are absent.[7,30]

The use of molecular diagnostic tools is elucidating patterns of HPIV-4 infections. A large, retrospective study conducted in Colorado between 2009 and 2012 showed that HPIV-4 had year-round prevalence, with biennial peaks during the fall of odd-numbered years (Fig. 223.1).[35–37]

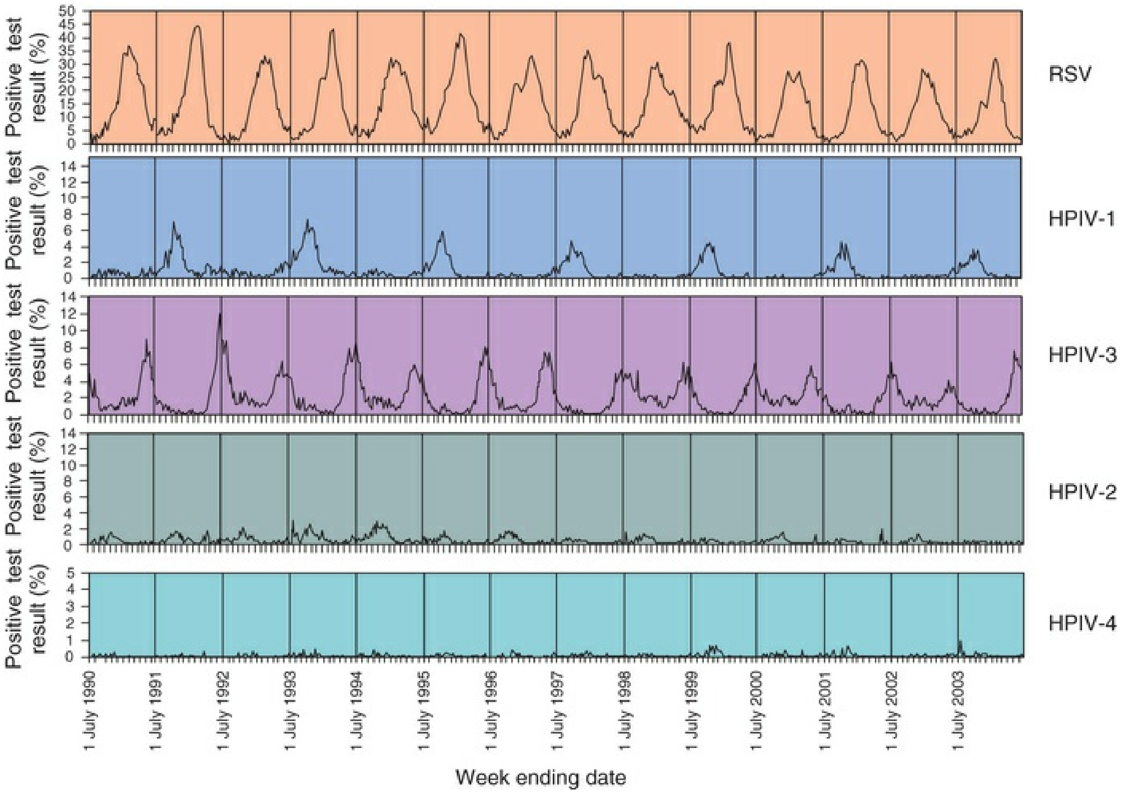

FIGURE 223.1 Seasonal trends of human parainfluenza virus (HPIV) infections are shown by the percentage of tests positive for serotypes 1, 3, 2, and 4 reported to the National Respiratory and Enteric Viruses Surveillance System (NREVSS) by week from July 1990 through June 2004. The percentage of antigen detection tests positive for respiratory syncytial virus (RSV) reported to NREVSS is shown for comparison. Notice that RSV and HPIV-4 have different axis scales than the other HPIV serotypes. (Modified from Fry AM, Curns AT, Harbour K, et al. Seasonal trends of human parainfluenza virus infections: United States, 1990–2004. Clin Infect Dis 2006;43:1016–1022.)

The age of primary infection varies by serotype. By 12 months of age, about 50% of infants have serologic evidence of HPIV-3 infection, and by 5 years of age, most children have been infected with HPIV-3.[35,38,39] In contrast, only 50% to 75% of 5-year-old children are seropositive for HPIV-1 and -2. Acquisition of HPIV-4 occurs during preschool years, following the pattern observed with HPIV-1 and -2.[40] A prospective surveillance study conducted in Houston, Texas, showed that rates of primary infection in the first and second year of life were 62 and 81 per 100 child-years, respectively.[30]

Infection with HPIV-3, the HPIV type that most closely resembles RSV, frequently occurs in young infants and is a prominent cause of bronchiolitis or pneumonia. Infections with HPIV-1 and HPIV-2 occur most commonly in children between 1 and 5 years of age. HPIV-4 infections are common in toddlers attending childcare centers and older children (mean age, 4 years) requiring hospitalization with more severe disease (Table 223.1).[35,36]

TABLE 223.1

Clinical and Epidemiologic Characteristics of Human Parainfluenza Virus Infections

Characteristic	HPIV-1	HPIV-2	HPIV-3	HPIV-4
Age	1–5 yr	2–6 yr	<6 mo	1–4 yr
Seasonality	Fall, odd-numbered years	Year-round, may follow HPIV-1	Endemic; spring/summer	Year-round with biennial peaks in the fall or winter of odd-numbered years
Most common clinical manifestation	Croup ++	Croup +	LRI (pneumonia, bronchiolitis)	URI ++ and LRI + (not croup)
Viral shedding[a]	2 wk	1 wk	3 wk	~1.5 wk
Hospitalization rates[3]	0.32–1.59/1000	0.1–0.86/1000	0.48–2.6/1000	Unknown

[a] In immunocompetent children.

HPIV, human parainfluenza virus; LRI, lower respiratory tract infection; URI, upper respiratory tract infection; +, less common; ++, more common.

Traditionally, HPIVs have been considered the second most common cause of hospitalization for respiratory disease in children.[3,41] HPIVs are associated with 30% to 40% of all acute respiratory tract infections in infants and children, and in the United States, they are responsible for 7% of all hospitalizations for fever or acute respiratory illness in children younger than 5 years of age.[3,7] Annual rates of HPIV-related hospitalization for children younger than 5 years of age vary from 1.0 to 5.1 per 1000 children.[7,8,42] Based on a 4-year longitudinal study, rates of hospitalization for US children younger than 5 years of age were similar for HPIVs, HMPV, and influenza virus: 1.02, 1.2, and 0.9 per 1000 children, respectively. Rates of hospitalization for RSV in the same population were threefold higher (3 of 1000).[3,43]

Rates of hospitalization for bronchiolitis, croup, and pneumonia due to HPIV infections in children younger than 5 years of age were estimated in a 12-year longitudinal study (1998–2010). The mean annual estimates were 0.2, 0.4, and 0.5 hospitalizations per 1000 children for bronchiolitis, croup, and pneumonia, respectively. The estimated annual costs attributed to these three conditions exceeded $250 million.[42] Most hospitalizations occurred for children younger than 2 years of age. Pneumococcal vaccination has been associated with a reduction in the incidence of pneumonia in infants with HPIV and other respiratory viruses, suggesting that pneumococcus is an important pathogen in the development of virus-associated pneumonia.[44]

HPIVs also cause acute respiratory illness with substantial morbidity and mortality rates in immunocompromised patients, those with underlying chronic cardiopulmonary conditions, and in the elderly.[5,6,45]

Transmission

HPIVs, particularly HPIV-3, are highly transmittable. Similar to RSV, HPIVs are transmitted from direct, close person-to-person contact through large respiratory tract droplets and by exposure to contaminated fomites. Climatologic factors may impact the shedding of HPIVs; in vitro studies have shown that aerosol particles of HPIV-3 survive longer when the relative humidity is 20% rather than 50% or 80%.

Infection most likely is transmitted by hands contaminated with secretions containing virus, followed by autoinoculation. An adult volunteer study demonstrated that HPIV was not transferable readily to the fingers of other volunteers after 20 minutes on contaminated hands.[46] If kept from drying, HPIVs survive on porous surfaces for up to 4 hours and on nonporous surfaces for as long as 10 hours.[47]

In closed settings, HPIV-3 infection occurs in virtually all exposed children. Secondary attack rates for HPIV-1 and HPIV-2 are 65% to

79%.[2] The usual incubation period for HPIV infection is 2 to 6 days.[22] Depending on the serotype, children with primary HPIV infection can shed virus from 1 week before the onset of symptoms to more than 3 weeks after symptoms resolve. Children with primary HPIV-1 infection shed cultivatable virus for 4 to 7 days and viral RNA, which is measured by polymerase chain reaction (PCR), for up to 2 weeks.[35] In the Houston Family Study, about 17% of children infected with HPIV-3 shed virus for as long as 3 to 4 weeks (see Table 223.1).

Nosocomial infections and outbreaks of HPIV-3 infection are associated with high attack rates. Outbreaks in neonatal nurseries and in bone marrow transplantation units have been reported.[48–53]

Clinical Manifestations

HPIVs cause a variety of upper and lower respiratory tract illnesses (Fig. 223.2), which vary by age, virus serotype, and season. Most primary infections are symptomatic, and disease prevalence is greater among outpatients than inpatients. In healthy children, most illnesses involve the upper respiratory tract, and up to 35% of cases are complicated with otitis media.[54,55]

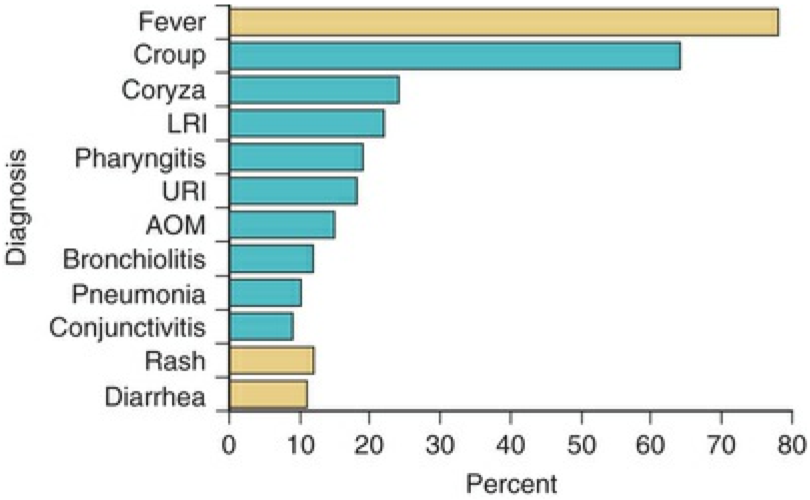

FIGURE 223.2 Clinical illnesses caused by parainfluenza viruses. *Orange* indicates systemic symptoms, and *blue* indicates respiratory symptoms. AOM: acute otitis media; LRI, lower respiratory tract infection; URI, upper respiratory tract infection. (Modified from Reed G, Jewett PH, Thompson J, et al. Epidemiology and clinical impact of

parainfluenza virus infections in otherwise healthy infants and young children <5 years old. J Infect Dis 1997;175:807–813; Frost HM, Robinson CC, Dominguez SR. Epidemiology and clinical presentation of parainfluenza type 4 in children: a 3-year comparative study to parainfluenza types 1–3. J Infect Dis 2014;209:695–702).

HPIV-1 and HPIV-2 typically are associated with croup, HPIV-3 with bronchiolitis and pneumonia, and HPIV-4 with mild URIs in children and adults. HPIV-4 has been associated with severe LRIs in patients with underlying medical conditions.[35,36,39,56] Croup is the most common HPIV-associated diagnosis.[13,57]

Upper Respiratory Tract Disease.

In children, HPIVs account for about 20 % of all URIs.[58–60] Infection typically starts with coryza, cough, rhinorrhea, pharyngitis without cervical lymphadenopathy, and low-grade fever. All four serotypes have been recovered from children and adults with the common cold.[33] URI is the typical manifestation of HPIV infection in immunocompetent adults.

Croup.

Croup (i.e., laryngotracheobronchitis) is a term used to encompass a heterogeneous group of illnesses that affect the larynx, the trachea, and the bronchi. Croup affects about 3% of children annually, with a peak incidence between ages 6 months and 3 years.[13,57] The incidence is 1.5 to 2 times higher among males than females.

HPIVs, especially HPIV-1, are the most frequent cause of croup, accounting for almost 75% of cases.[13,61,62] Croup is characterized by fever, laryngeal obstruction, dyspnea, inspiratory stridor, and a hoarse, barking cough. In mild to moderate cases, symptoms typically last 3 to 5 days. progression is unpredictable, however, and sudden respiratory failure can occur.

In cases with severe stridor, differentiation from epiglottitis can be facilitated by lateral neck radiography. The typical finding in children with croup is subglottic narrowing (i.e., steeple sign).[63] Repeated episodes of spasmodic croup can follow, and abnormalities in lung function can persist for several years in some children.[64] It is unclear whether disposition precedes or results from viral infection.

Bronchiolitis.

Historically, HPIVs have been considered the second in frequency to RSV as a cause of bronchiolitis. However, the use of molecular diagnostics has identified other respiratory viruses more frequently than HPIV as etiologic agents of bronchiolitis.[65,66] All four types of HPIV can cause bronchiolitis, but HPIV-1 and HPIV-3 have been reported most frequently.[3,8,42]

More than 80% of cases of bronchiolitis occur during the first year of life, and most affect infants are younger than 6 months of age. HPIV-1 and HPIV-3 cause 5% to 15% of bronchiolitis cases in children, respectively, and approximately 0.2 per 1000 children with HPIV bronchiolitis require hospitalization.[42] Most hospitalizations for bronchiolitis occur from November through April. Using US National Hospital Discharge Survey data over 18 years, HPIV-related bronchiolitis hospitalizations in children younger than 1 year of age peaked earlier during odd-numbered years than even-numbered years, resulting in a longer season.[8]

Predominant symptoms include fever, tachypnea, retractions, expiratory wheezing, rales, and air trapping. Bronchiolitis caused by HPIVs is clinically indistinguishable from that caused by other respiratory viruses.

Virus-induced asthma and asthma exacerbations are more commonly associated with respiratory viruses other than HPIVs in children and adults.[67,68] Nevertheless, asthma is diagnosed commonly in children older than 2 years of age with any type of HPIV infection.[3,36]

Pneumonia.

All HPIV types can cause pneumonia. HPIV-1, -2, and -3 are responsible for approximately 10% of pneumonia cases in the outpatient setting and 7% to 15% of cases in hospitalized children of all ages.[69–73] The percentage of hospitalized children diagnosed with HPIV pneumonia, including those requiring admission to a pediatric intensive care unit, is higher in the first year of life, and as with bronchiolitis, it most often is associated with HPIV-3 infection.[42,74]

HPIV pneumonia occurs more frequently and is more severe in chronically ill or immunocompromised children.[36,75] In hematopoietic stem cell transplant (HSCT) recepients, HPIV infection can result in refractory pneumonia with prolonged viral shedding, viral dissemination, and high mortality rates.[5,26,76]

Otitis Media.

In 10% to 35% of children with an HPIV URI, acute otitis media (AOM) follows 3 to 4 days after onset of the URI.[54,55,77–81] In a study conducted over 20 years among previously healthy children younger than 5 years of age using culture techniques, the rate of AOM was higher for HPIV-3 than for HPIV-1 and HPIV-2 infection.[7] Other data have confirmed these findings and also suggest that HPIV-4 is a common cause of AOM in children.[36]

Other Manifestations.

Neonates, particularly premature infants, infected with HPIV can have apnea.[3,52] Fever and febrile seizures have been reported in young infants with HPIV infections, and it is the most common finding in older children with HPIV infections regardless of the HPIV type.[36] A study conducted from 2000 to 2004 and enrolling 2798 children younger than 5 years of age showed that HPIVs accounted for 6.8% of all hospitalizations for fever or acute respiratory illness, or both.[3]

Conjunctivitis and gastroenteritis also occur frequently, with no HPIV type associations.[33,36] Cases of parotitis, myopericarditis, aseptic meningitis, encephalitis, and Guillain-Barré syndrome are reported, suggesting possible neurotropism of some strains.[82–84] Disseminated infection can occur in immunosuppressed people.[85]

Laboratory Findings and Diagnosis

Specific diagnosis requires identification of the virus in respiratory secretions. PCR is the preferred diagnostic test because of its high sensitivity and rapidity. Because HPIVs rarely are isolated in otherwise healthy asymptomatic children, detection of the virus in the context of an acute respiratory illness suggests causality.[86,87]

Respiratory specimens for viral diagnosis should be collected early in the course of illness. Nasopharyngeal aspirates or swabs are the preferred samples. Rates of HPIV detection may be similar with a nasopharyngeal swab or NP aspirate, and a paired nasopharyngeal and oropharyngeal swab may increase sensitivity.[88,89] Direct sampling by bronchoalveolar lavage or lung biopsy may be necessary to identify the virus and establish causality in immunocompromised hosts with lower respiratory tract disease.[90] For virus isolation, immediate placement of samples on ice (or refrigeration at 4°C) and transport to the laboratory for tissue culture inoculation are critical.

Reverse transcriptase PCR (RT-PCR) has replaced tissue culture and indirect immunofluorescence(IF) techniques for the identification of all HPIV types.[91,92] RT-PCR is especially useful for the diagnosis of HPIV infections in critically ill patients, especially those who are immunocompromised.[93–95] Rapid antigen diagnostic tests using IF techniques are available for HPIV-1, -2, and -3, and although specific, they are less sensitive than PCR.[96] Serologic assays based on hemagglutination inhibition or enzyme immunoassays can be used to detect serum IgM or IgG antibodies against HPIV, but they have limited value in disease management.

Treatment

No specific antiviral therapy is available for HPIV infection. Most HPIV infections are self-limited in immunocompetent hosts and do not require treatment. For the management of croup, dexamethasone and nebulized epinephrine have been associated with improved clinical outcomes.[57] Management of bronchiolitis is supportive.

Ribavirin has in vitro activity against HPIVs. The use of ribavirin (mostly inhaled) has been reported for immunocompromised children and adults with severe HPIV pneumonia with or without concomitant administration of immune globulin intravenous (IGIV); however, controlled studies are lacking.[26,97,98]

DAS181 is a sialidase fusion protein with activity against influenza and HPIV that removes sialic acid–containing receptors from the surface of respiratory epithelial cells, preventing virus binding. Use of DAS181 for the treatment of HPIV LRI in lung and HSCT patients, including children, has reduced viral loads and improved clinical symptoms.[99–103]

Other novel antiviral agents have activity against HPIV. The hemagglutinin-neuraminidase inhibitors (i.e., BCX 2855 and BCX

2798) appear promising. Although there are no data on use in humans, the agents have potent in vitro activity against HPIV and appear to be beneficial in animal models of infection.[104–106] Nitazoxanide, originally developed as an antiprotozoan agent, has broad antiviral activity. In a randomized, placebo-controlled clinical trial enrolling patients with laboratory-confirmed influenza, nitazoxanide treatment reduced viral shedding and duration of symptoms.[107] Its potential role in the treatment of HPIV infections is not known.[108] There are anecdotal reports of using interferon α-2b in HPIV-infected patients.[109]

During the acute infection, efforts should be aimed at decreasing healthcare-associated infections. In addition to standard precautions, contact precautions are recommended for hospitalized infants and young children for the duration of illness. Prevention of environmental contamination by respiratory tract secretions and careful hand hygiene should control healthcare-associated spread.

Special Considerations

Immunocompromised Hosts

Parainfluenza infections are associated with substantial morbidity and mortality for children and adults with congenital or acquired immunodeficiencies, including HSCT and solid-organ transplant (SOT) recipients, children with cancer undergoing chemotherapy, and children with severe T-lymphocyte deficiencies. Although nosocomial infections have been described, most HPIV outbreaks in transplantation units coincide with the peak incidence of these infections in the community.[110]

Hematologic Malignancies.

In children with leukemia or lymphoma, HPIV has been detected in 10% of cases and was the second most common respiratory viral infection identified. Ninety percent of infections were acquired in the community, and 61% were caused by HPIV-3. Neutropenia and lymphopenia at onset of infection were associated with progression to LRI.[111]

Hematopoietic Stem Cell and Solid-Organ Transplantation.

Among patients undergoing HSCT, the incidence of HPIV infections ranges from 4% to 7%, of which up to 40% progress to LRI.[90,106,112] In this setting, HPIV pneumonia is associated with prolonged viral shedding, viremia, and mortality rates of up to 40%. Most cases of HPIV pneumonia have been associated with HPIV-3.[26,48,113–116]

The most severe illnesses and 90% of the deaths related to HPIV pneumonia occur in the first 100 days after transplantation, when lymphopenia is most pronounced. Use of unrelated donors, myeloablative conditioning regimens, and high-dose corticosteroids for the treatment of graft-versus-host disease are identifiable risk factors for progression to pneumonia.[26,112,117] Other respiratory copathogens frequently are identified in patients with HPIV-3 pneumonia and may contribute to the significant morbidity and mortality rates.

Solid-organ transplant recipients, especially those undergoing lung transplantation, have increased HPIV-associated mortality rates and severe morbidity, including chronic rejection and development of bronchiolitis obliterans.[118–121] Airflow decline has been linked to HPIV pneumonia and HPIV URIs in HSCT recipients.[122]

Congenital or Acquired Immunodeficiencies.

Patients with primary immunodeficiencies can have prolonged HPIV shedding, particularly when infected with HPIV-3. Fatal giant cell pneumonia has been described in children with severe combined immunodeficiency and IFNγ receptor deficiency syndrome.[123,124]

In children infected with the human immunodeficiency virus type1 (HIV-1), HPIV infections have been associated with increased morbidity and mortality rates in developing countries.[75,125] Prolonged shedding occurs in HIV-infected children.[126,127]

Prevention

The lack of durable immunity and full understanding of the mechanisms responsible for immune protection have hampered the development of HPIV vaccines.[128] Formalin-inactivated vaccine preparations developed in the late 1960s were immunogenic in infants and did not cause enhanced disease, but they did not confer protection.[129] Subsequently, subunit vaccine candidates containing HN or F protein showed some protection in animals against LRI but failed to protect against URI and have not been evaluated in human clinical trials.[130]

Live, attenuated and subunit vaccine candidates are being studied in humans. Two strategies have been used for the development of live, attenuated HPIV-3 vaccines: use of an antigenically related strain (i.e., bovine PIV-3) or Sendai virus (murine PIV-3), and use of a cold-adapted HPIV-3 strain. These candidate vaccines have been safe and well tolerated in children and adults.[131–134] Improved seroconversion rates and immunogenicity have been demonstrated with live, attenuated candidate vaccines administered intranasally.[135,136]

Reverse genetics has allowed the development of recombinant rHPIV-1, -2 and -3 and chimeric bovine/human PIV-3 virus (rB/HPIV-3) candidate vaccines that are undergoing testing in seropositive and seronegative children. Early results are promising.[137–142] This technology allows rapid production of the vaccine with minimal risk for contamination.

Key Points

Diagnosis and Management of Human Parainfluenza Virus (HPIV) Infections

Microbiology

- Enveloped, negative-sense, single-stranded RNA paramyxovirus
- Five types: HPIV-1, -2, -3, -4A, and -4B

Epidemiology

- Different HPIVs have distinct epidemiologic patterns
  - HPIV-3 is endemic with peaks in the spring.
  - HPIV-1 and HPIV-2 cause outbreaks of croup.
  - HPIV-4 causes biennial peaks in the fall and winter.

- Age of primary infection varies for each serotype.
- By age 5 years, almost all children have been infected with all HPIVs.
- HPIV infection does not confer protective immunity, and reinfections are common throughout life.
- HPIVs are transmitted from person to person by direct contact and exposure to contaminated droplets and fomites.

Clinical Features

- HPIVs account for 18% to 45% of all upper respiratory tract illnesses in children.
- Acute otitis media occurs in 10% to 35% of children after HPIV upper respiratory tract infection.
- HPIV-1 and -2 are the most frequent causes of croup in children 1 to 5 years of age.
- HPIV-3 is associated predominantly with bronchiolitis and pneumonia (children <1 year old).
- HPIV-4 is mostly associated with upper respiratory infections in healthy children.
- HPIV infection can result in refractory pneumonia, with a mortality rate of approximately 40% for hematopoietic stem cell transplant patients.

Diagnosis

- Polymerase chain reaction (PCR), direct fluorescent antibody, or viral culture from respiratory secretions (nasopharyngeal swab or aspirate)
- PCR is the preferred method, especially for an HPIV-4 diagnosis and immunocompromised, critically ill children and elderly persons.

- Bronchoalveolar lavage or lung biopsy may be required to confirm the cause of infection in immunocompromised or hematopoietic stem cell transplant (HSCT) patients.

Treatment

- Most HPIV infections are self-limited in immunocompetent hosts and do not require treatment.

- Ribavirin (inhaled) with or without immune globulin intravenous (IGIV) has been used in immunocompromised patients with severe pneumonia.

- New antiviral therapies include DAS181 and hemagglutinin-neuraminidase inhibitors.

- Several vaccine candidates (i.e., recombinant and live, attenuated viruses) are being tested.

- Assiduous infection prevention measures are critical to prevent nosocomial transmission, especially for HSCT recipients.

Mumps Virus

Yvonne A. Maldonado, Avinash K. Shetty

Mumps (i.e., epidemic parotitis) is an acute, vaccine-preventable disease of childhood that typically involves swelling of one or both parotid glands, although many different organs can be infected.[1] Childhood mumps has become uncommon in the United States since the widespread implementation of measles-mumps-rubella (MMR) vaccination. Reports of mumps outbreaks involving highly vaccinated populations in the United States and other countries have prompted re-evaluation of current mumps vaccination strategies.[2–6]

Description of the Pathogen

Mumps virus (MuV) is a member of the *Rubulavirus* genus in the Paramyxoviridae family. MuV has a single-stranded, negative-sense, nonsegmented RNA genome of 15,384 nucleotides. The viral genome is contained in a helical nucleocapsid enclosed in a trilayered envelope studded with two surface glycoproteins possessing hemagglutinin and neuraminidase (HN protein) and cell fusion (F protein) activities.[7] MuV contains seven structural proteins, including a nucleocapsid protein, phosphoprotein, matrix protein, high-molecular-weight protein, small hydrophobic (SH) protein, HN protein, and F protein.

There is one serotype of the virus. The gene for the SH protein is the most variable part of the MuV genome. Based on the gene sequences for the SH and HN proteins, the MuV has been classified into 12 genotypes.[8,9]

MuV grows well in many human and monkey tissues, and in embryonated eggs. Cytopathic effects in cell culture include rounding and fusion of cells into giant multinucleated syncytia and the formation of intracytoplasmic inclusions.[10]

Epidemiology

Mumps occurs worldwide and affects only humans; there is no animal reservoir. In the absence of vaccination, most people acquire infection by young adulthood. Epidemic parotitis is caused solely by MuV. Endemic mumps is most common in winter and early spring in temperate climates. Although male and female infection rates are similar, males are more likely to have complications.

In the United States, the reported incidence of mumps declined after the introduction of mumps vaccine in 1967 and recommendation for routine childhood immunization in 1977. After expanded recommendations for a 2-dose MMR vaccine schedule for measles control in 1989, mumps cases declined further.[11] During the 2001–2003 period, fewer than 300 mumps cases (i.e., incidence of 0.1 case/100,000 people) were reported annually; this was a 99% decline from the 185,691 reported cases in 1968. However, an increase in cases occurred late in 2005 (Fig. 224.1).[12] From 2006 to 2010, several large-scale mumps outbreaks occurred in 2-dose vaccinated populations, especially among school-aged children and young adults in settings with high contact rates (e.g., college campuses).[12–19] These outbreaks highlight the importance of early detection and timely reporting of cases to health departments.[2] Transmission of mumps within hospital settings also can occur.[20]

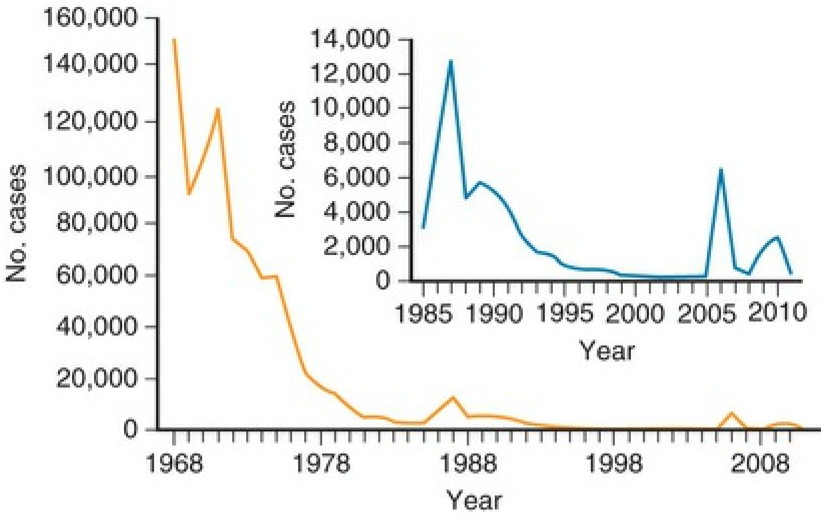

FIGURE 224.1 Number of reported cases of mumps by year in the United States, 1968 to 2011.

In 2006, a major mumps resurgence occurred in eight Midwestern states, resulting in 6584 cases (i.e., incidence of 2.2 cases/100,000 people) (Fig. 224.2). The MuV isolated was a genotype G strain. Almost 40% of patients were between 18 and 24 years of age and were mainly college students who had received 2 doses of MMR vaccine.[16] Most people had parotitis, and many had complications of orchitis, meningitis, encephalitis, deafness, oophoritis, mastitis, and pancreatitis.

FIGURE 224.2 Outbreak-related mumps cases by state, January 1 to May 2, 2006.

Between June 28, 2009 and June 27, 2010, a large outbreak of 3502 mumps cases occurred in the Northeast.[18] The source case was an 11-year-old US resident, who developed mumps while attending a summer camp in New York soon after his return from the United Kingdom.[17] The outbreak occurred primarily among 2-dose vaccinated school students between 13 and 17 years of age, who were members of the tradition-observant Jewish community.[18]

During 2010, another mumps outbreak (505 cases) occurred on the US territory of Guam in a highly vaccinated population; it primarily involved school-aged children.[15] In September of 2011, a mumps outbreak occurred on a university campus in California.[2] In August of 2011, the presumed source patient, a 21-year-old, unvaccinated man, developed mumps after his return from Western Europe, where mumps was circulating. Subsequently, 29 mumps cases occurred among university students; 22 (76%) students had received 2 doses of MMR vaccine.[2]

Mumps outbreaks among highly vaccinated adolescents also have occurred in the Netherlands, Spain, Israel, Korea, and Australia.[3,4,21] Strain change and waning immunity is hypothesized to play a role in mumps outbreaks among vaccinated people, and experts have proposed new mumps vaccine development.[6,22]

The incubation period of mumps is 16 to 18 days (range, 12–25 days).[23,24] An estimated 80% to 90% of nonimmune household contacts become infected.[25] Attack rates for development of clinically apparent disease have been substantially lower in recent outbreaks, especially for those who received 2 doses of MMR vaccine.[14] Patients are most contagious 1 to 2 days before symptom onset and for 5 days thereafter; MuV has been isolated from saliva 7 days before symptoms and up to 9 days after the appearance of parotitis. Clinical and subclinical infections provide lifelong immunity; reinfection occurs rarely. Children with subclinical disease are infectious.[26]

Pathogenesis and Immune Response

Mumps infection is acquired after contact with infected respiratory secretions. Viral replication in the nasopharyngeal mucosa and regional lymph nodes is followed by primary viremia, which results in spread of infection to multiple organs, including the central nervous system (CNS) and glandular epithelium.[7,27] Parotid gland pathology includes diffuse interstitial edema and serofibrinous exudate with infiltration of lymphocytes and macrophages. The ductal epithelium undergoes necrosis with intraluminal accumulation of lymphocytes and debris.[28]

Orchitis results from direct MuV infection of the testes; MuV has been isolated from testicular biopsy specimens of the affected gland within the first few days of symptoms.[29] Histologic changes within the testes include interstitial edema and lymphocytic infiltration.[30] Focal destruction of the germinal epithelium can occur.

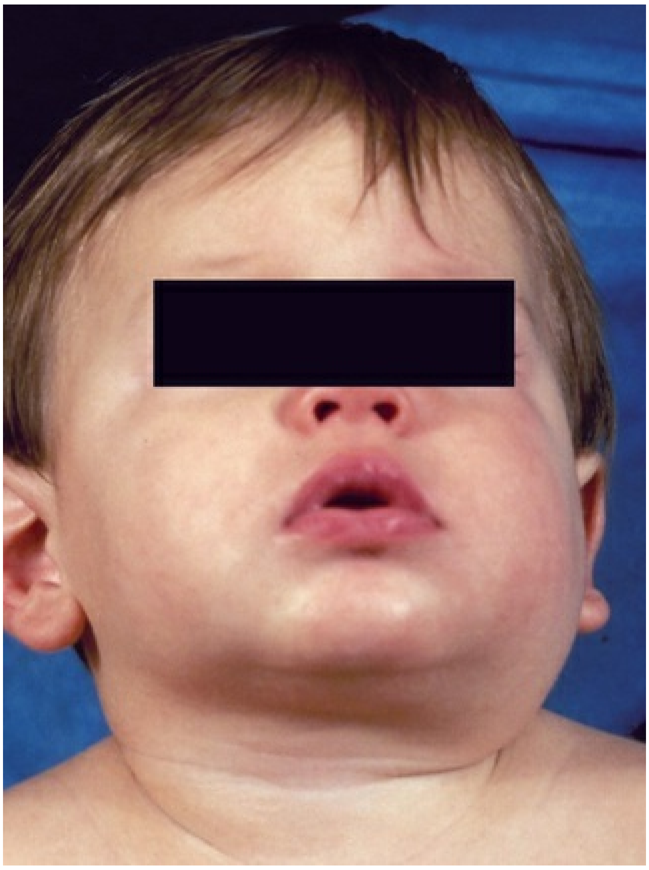
MuV infection of the CNS is common.[7] The virus probably enters the CNS through the choroid plexus and infects the choroidal epithelium and ependymal cells lining the ventricles.[31] Enlargement of the lateral and third ventricle (i.e., hydrocephalus) has been observed in animal models and humans. The pathogenesis of virus-induced hydrocephalus is postulated to be accumulation of infected ependymal cell debris in the cerebrospinal fluid (CSF).[7] Mumps encephalitis occurs when infection spreads to the brain parenchyma along neuronal pathways.

Specific immunoglobulin M (IgM), IgA, and IgG antibodies are produced in response to mumps infection.[32–35] Virus-specific secretory IgA appears concurrently with the cessation of viral shedding in saliva. Intrathecal synthesis of mumps IgG and IgM antibodies has been demonstrated, along with production of interferon γ by activated cytotoxic T lymphocytes in the CSF.[36–39]

Clinical Manifestations

One third of patients with mumps infection have subclinical or mild respiratory tract illness.[40,41] The most common manifestation is painful parotid swelling (i.e., 95% of symptomatic patients),[41] which usually is unilateral at the onset of illness and later becomes bilateral in 70% of cases. Prodromal symptoms, including fever, malaise, headache, and anorexia, typically precede parotitis by 12 to 24 hours. Earache on the side of parotitis and discomfort with eating or drinking acidic foods are common.

The swollen parotid gland lifts the earlobe upward and outward, and the angle of the mandible is obscured (Fig. 224.3). The opening of the Stensen duct on the buccal mucosa is edematous and erythematous. Trismus can occur. About 10% of submandibular and sublingual glands can be affected.[1] Presternal edema can be prominent. Morbilliform rash has been reported.[42] Systemic symptoms, including fever, usually resolve within 3 to 5 days, and parotitis subsides within 7 to 10 days. Adolescents and adults have more severe disease than young children.



[redacted]

FIGURE 224.3 Toddler with mumps parotitis. (Courtesy of A. Margileth.)

The differential diagnosis of parotitis is broad and includes bacterial (suppurative) parotitis, parotid duct stone, drug reactions, recurrent parotitis of childhood, parotid tumor, and Sjögren syndrome. Other viruses, such as Epstein-Barr virus, influenza, coxsackievirus A, echovirus, and parainfluenza virus types 1 and 3, can cause parotitis and are usually responsible for “recurrent mumps” (Fig. 224.4). Children with human immunodeficiency virus (HIV) infection can have chronic bilateral parotid swelling that is not caused by MuV infection. Failure to use a strict case definition of mumps infection based on clinical and laboratory criteria or confirmatory laboratory testing can lead to an overestimation of the number of mumps cases in a population.[43,44]

Complications

Central Nervous System Infection

MuV is highly neurotropic, and the degree of neuropathogenicity may depend on the virus genotype.[45] The molecular determinants of MuV neuropathogenesis are unclear.[46] Although CSF pleocytosis occurs in more than 50% of people with mumps parotitis, less than 10% have symptoms of meningitis.[1,47] Parotitis does not develop in about 50% of patients with mumps meningitis.[48] MuV can be isolated from CSF in 40% to 50% of patients with mumps meningitis.[49]

CNS disease due to MuV is threefold higher in males than females. Meningitis is more common than encephalitis.[23,50] Encephalitis may develop in 0.1% of infections.[1] Meningitis typically occurs 3 to 10 days after the onset of parotitis, but can precede or occur without parotitis. Patients have fever, headache, vomiting, lethargy, and nuchal rigidity; 20% of patients have seizures.[48] The CSF white blood cell count (WBC) usually is less than 1000 cells/mm^3, with lymphocytes predominating. The CSF protein level is normal or mildly elevated, and the CSF glucose concentration is decreased in 30% of cases.[51] CSF pleocytosis can persist for prolonged periods, suggesting persistent infection.[52]

In general, the course is self-limited with no sequelae, but ataxia, behavioral problems,[48,53] aqueductal stenosis with hydrocephalus,[54,55] and sensorineural deafness can occur.[56,57] In Japan, where mumps remains endemic because measles-rubella vaccine is used instead of MMR vaccine, the incidence of hearing loss among children with mumps is 1 case per 1000 people.[58] Other complications of mumps include paralysis[59] and neuroretinitis.[60] About 1.4% of people with encephalitis die.[61]

Orchitis

Orchitis develops in 14% to 35% of postpubertal males with mumps.[62,63] Males between 15 and 29 years of age are at highest risk. Orchitis is uncommon in prepubertal males.[25,41]

Symptoms begin 4 to 8 days after the onset of parotitis, but orchitis can occur before or in the absence of parotitis. Testicular involvement usually is unilateral, and epididymitis is associated with orchitis in most cases.[64] Clinical findings include fever, malaise, vomiting, lower abdominal pain, and testicular pain. The testicle typically is swollen and tender for 3 to 7 days. MuV has been isolated from seminal fluid, and viral RNA has been detected in semen several weeks after infection.[65] An elevated serum C-reactive protein level is common.[66]

Treatment of mumps orchitis is symptomatic, with bed rest and the use of scrotal support, ice packs, and anti-inflammatory agents.[64] Complete recovery occurs for about 50% of males with mumps orchitis; 50% have some testicular atrophy. Infertility rarely occurs, although a decrease in sperm count and sperm motility can occur in up to 25% of patients.[64,67]

Other Sites of Infection

Hematuria, proteinuria, and transient alterations in creatinine clearance can occur in children with mumps.[68] Glomerulonephritis usually is self-limited, and death from renal failure is unusual.[69]

Arthralgia, polyarticular migratory arthritis with effusion, and monoarticular arthritis are described.[70] Signs usually appear 1 to 3 weeks after the onset of parotitis, but they can occur before or in the absence of parotitis. Joint complaints are threefold to fourfold more common among males, and the average age of occurrence is 24 years.[70,71] Large joints (i.e., knee, hip, wrist, ankle, and shoulder) are affected most frequently. The duration of joint symptoms ranges from 2 days to 6 months. Recovery with no evidence of persistent or recurrent symptoms is usual.

Electrocardiographic abnormalities consistent with myocarditis are reported in up to 15% of patients (often adults) with mumps.[72] Abnormalities resolve within 2 to 4 weeks, although sequelae are reported.[73]

Pancreatitis can occur in about 4% of mumps infections and may cause mild epigastric pain[74]; severe hemorrhagic pancreatitis has been reported.[75] The role of MuV in the development of insulin-dependent diabetes mellitus is controversial. Cases have occurred after mumps outbreaks, but no causal relationship has been established.[76,77]

Oophoritis can occur in 5% of postpubertal women with mumps.[1] Other rare complications include mastitis,[25] thyroiditis,[78] thrombocytopenic purpura,[79] and hepatitis with acute cholecystitis.[80]

Mumps in Pregnancy

Compared with uninfected women, women with mumps during pregnancy have no increase in the risk of delivering an infant with congenital malformations.[81,82] The rate of spontaneous abortion among women who acquire mumps during the first trimester of pregnancy is increased in some studies but not in others.[82,83]

Gestational mumps infection has been implicated in the development of endocardial fibroelastosis (EFE) in offspring. Although many infants with EFE have had positive skin test responses to mumps antigen,[84,85] MuV has not been isolated from affected infants.[86,87] PCR has detected MuV genome in more than 70% of myocardial samples from 29 patients with autopsy-proven

EFE.[88] Perinatal mumps infection with parotid swelling, pneumonia, and pulmonary hypertension has been reported.[89–92]

Diagnosis

The diagnosis of mumps is suspected in patients with parotitis for 2 or more days and no other apparent cause. Laboratory findings include elevated serum amylase levels during the first week of illness and a low or normal WBC count with a relative lymphocytosis. Mumps infection can be confirmed by positive MuV culture result, detection of the viral genome by reverse transcriptase PCR (RT-PCR), positive serum mumps-specific IgM antibody test result for a single serum sample, or demonstration of a fourfold or greater rise in mumps-specific IgG antibody titers between acute and convalescent serum samples.[23,24,43,93]

Practitioners should consult their local health department for recommendations for optimal specimen collection and submission.[94] If a patient has clinical features compatible with mumps, buccal and oral swabs should be obtained, and blood should be drawn for serologic testing. Suitable specimens for MuV isolation include a throat swab or Stensen duct exudates, CSF, and urine. Samples for virus detection should be collected as soon as mumps is suspected. This is particularly important in immunized patients because the quantity and duration of virus shedding may be decreased.[95] Clinical specimens should be obtained within 1 to 3 days and not more than 8 days after the onset of parotitis.[23,24]

MuV can be isolated readily from saliva, throat, urine, and CSF.[1,23] MuV can be isolated from the oropharynx 7 days before and up to 9 days after symptom onset.[96] Virus is found in urine for up to 2 weeks and in CSF for 8 or 9 days after symptom onset.[97] Cell culture shows the typical cytopathic effect of cellular degeneration and syncytium formation, and virus is confirmed by hemagglutination inhibition assays or immunofluorescent antigen detection.[98,99]

More rapid and sensitive RT-PCR assays have replaced viral culture in routine practice.[24] PCR can detect viral RNA directly on clinical specimens and in CSF samples from children with aseptic meningitis.[100,101] RT-PCR also can detect MuV RNA in previously vaccinated children who develop mumps.[95]

Mumps-specific IgM and IgG antibodies can be measured by standard quantitative or semiquantitative serologic tests. The semiquantitative enzyme immunoassay (EIA) is the most frequently used test, and it is more sensitive than other labor-intensive serologic tests (e.g., hemagglutination inhibition, complement fixation, neutralization assays).[1,23,24,93,102,103]

The Centers for Disease Control and Prevention (CDC) test for mumps using a nonquantitative capture IgM EIA. A positive IgM test result indicates current or recent mumps infection. The optimal time for IgM testing may be 7 to 10 days after symptom onset.[102,103] Serologic confirmation can be challenging in vaccinated people.[1,24] Mumps IgM is less likely to be positive if the patient has previously received 1 (i.e., 50% positive)[102] or 2 doses of mumps vaccine (i.e., 13%–15% positive).[95] A positive IgG response indicates recent or past exposure to wild-type MuV or vaccine. A second serum sample should be obtained 2 to 3 weeks after symptom onset to verify IgG seroconversion.[104] In previously vaccinated people, mumps IgG levels already can be elevated in the acute phase sample. Mumps-specific IgM and IgG antibodies can be detected in CSF in cases of mumps meningitis.[105]

Treatment and Prevention

No specific antiviral therapy is available for mumps infection. Treatment is supportive.

Mumps Vaccine

The live, attenuated Jeryl Lynn strain (i.e., genotype A) of MuV vaccine currently used in the United States was licensed in 1967.[106,107] Mumps vaccine had been introduced globally in 120 countries by the end of 2013. Neutralizing antibodies develop in more than 90% of vaccine recipients after a single dose.[108] Concentrations of neutralizing antibody are considerably lower after vaccination than after natural infection,[109] but vaccine-induced immunity is long-lasting.[110] The correlate of protection induced by mumps vaccine is not well understood.[111,112]

Although the mumps vaccine was licensed for use in 1967, universal immunization was not recommended until 1977. Between

1985 and 1988, an increase in the number of mumps cases was observed (see Fig. 224.1), primarily in older school-aged children, college students, young adults, and children too young to be vaccinated.[19,113] The resurgence may be explained by failure to vaccinate all susceptible people during the 10 years after licensure of the mumps vaccine, resulting in a cohort of nonimmune older people.[114]

Mumps cases increased dramatically in England and Wales beginning in 2003 and 2004, and it peaked in 2005 with about 56,000 reported cases.[115,116] The highest attack rate was among adolescents and young adults born between 1983 and 1986. These people would not routinely have been offered MMR vaccination when introduced in 1988, and many in this age group could have received no vaccine or only 1 dose.[115] Declining immunization rates in the UK may account for an increase in mumps cases in younger children.[117]

Outbreaks of mumps have been reported in highly vaccinated US populations.[13–18] In some of these outbreaks, sustained transmission has occurred.[17,22] Outbreaks have been caused predominantly by genotypes not contained in the vaccine.[118] Partial vaccine failure due to strain change has been suggested to play a role,[6,119] but evidence is lacking from well-designed studies.[120,121] Infection also may result from waning immunity,[6,19,110,114,122,123] consistent with vaccine effectiveness estimates from the UK and serologic data from Finland.[124,125]

MuV induces low-avidity antibodies after vaccination and natural infection.[126] The protective efficacy of 1 dose of mumps vaccine based on postlicensure data is about 78% (range, 49%–92%); 2 doses provide an approximately 88% rate of protection (range, 66%–95%).[127,128] In the 2006 Midwestern outbreak, receipt of 2 doses of mumps vaccine was associated with substantially higher individual protection and a lower attack rate (2%) in one college with higher 2-dose vaccination coverage compared with an attack rate of 3.8% in another college with lower coverage.[12]

Outbreak analyses suggest that adolescents or young adults who receive 2 doses of vaccine but who reside in low-population rural communities, where opportunities for natural boosting by exposure to endemic disease is low, may be at higher risk for mumps infection when they move to more crowded living situations.[19] One hypothesis is that current population immunity of about 90% is lower than that needed to achieve community (herd) protection.[129] Higher rates of vaccination or newer, more effective mumps vaccine strategies may be required.[5,6,22]

Recommendations

Two doses of mumps vaccine are recommended and administered subcutaneously to children at 12 through 15 months of age and at 4 through 6 years of age[24,130] (Box 224.1). Mumps vaccine is given in combination products with measles and rubella immunization (i.e., MMR vaccine) or with measles, rubella, and varicella immunization (i.e., MMRV vaccine). Complete mumps immunization is particularly important for children approaching puberty. Children who have not received a second dose of vaccine should do so at a routine provider visit by 11 to 12 years of age. Routine use of mumps vaccine is not recommended for people born before 1957.[130] Immunization is not contraindicated in immune people.

Box 224.1

Recommendations for Mumps Vaccine

Evidence of Immunity to Mumps (Any of the Following)

- Documentation of age-appropriate vaccination with a live mumps virus–containing vaccine[a]
    - Preschool-aged children: 1 dose
    - School-aged children (i.e., grades K–12): 2 doses
    - Adults not at high risk: 1 dose
- Laboratory evidence of immunity
- Laboratory confirmation of disease
- People born before 1957

Routine Vaccination for Healthcare Personnel

- People born in or after 1957 without other evidence of immunity:

2 doses of measles-mumps-rubella (MMR) vaccine (>28 days apart)

- For unvaccinated personnel born before 1957 who lack laboratory evidence of mumps immunity or laboratory confirmation of disease, healthcare organizations should consider vaccinating personnel with 2 doses of MMR vaccine at the appropriate interval.

Outbreak Settings

- Children 1–4 years of age and adults at low risk; if affected by the outbreak, consider a second dose[b] of MMR vaccine
- Adults at high risk (i.e., international travelers and students at post–high school educational facilities) should be offered 2 doses of MMR vaccine
- Healthcare personnel born in or after 1957 who have received only 1 dose of MMR vaccine should be offered a second dose
- Healthcare personnel born before 1957 without other evidence of immunity should receive 2 doses of MMR vaccine during an outbreak of mumps

---

[a] Measles-mumps-rubella-varicella (MMRV) vaccine is not licensed for use in children >12 years old.

[b] Minimal interval between doses is 28 days.

Data from Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome and mumps, 2013: summary recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2013;62(RR-04):1–34.

Adverse Reactions

Allergic reactions, possibly due to the gelatin or neomycin component of the vaccine, are uncommon. Severe allergic reactions, including anaphylaxis, are rare.[24] Reported adverse events with a temporal association with the mumps component of MMR or MMRV vaccine, including fever, febrile seizures, aseptic meningitis, encephalitis, orchitis, and parotitis, are rare. Reported rates of all CNS reactions with the Jeryl Lynn vaccine strain range from 1 case in 50,000 to 1,000,000 doses of vaccine, a frequency lower than the background incidence observed in the general population.[131] An increase in the expected number of mumps vaccine–associated cases of meningitis occurred in Canada, Japan, and the UK during a period when the Urabe Am 9 strain of MuV was used in combination with a measles and rubella vaccine.[132–134]

Vaccine Contraindications

Vaccine virus has been isolated from the placenta of nonimmune women immunized 7 to 10 days before therapeutic abortion.[135] Virus has not been isolated from fetal tissue of immunized women, and no case of mumps vaccine–associated embryopathy has been reported. However, because of theoretical risks to the fetus, pregnant women should not be immunized, and conception should be avoided for 28 days after vaccination. Mumps vaccine is not transmitted from vaccinees to contacts and should be given when indicated to children whose mothers are pregnant.

Persons who are allergic to neomycin or gelatin should receive vaccine in a setting where they can be monitored and after consultation with an allergist. Most children with egg hypersensitivity can be immunized with MMR or MMRV. Skin testing of children allergic to eggs is not recommended because it is not predictive of reactions to MMR or MMRV vaccine.[24] Children with a significant hypersensitivity reaction after the first dose of MMR should be tested for immunity and, if immune, should not receive a second dose. Alternatively, they could be evaluated, possibly with skin testing, before receiving a second dose. Children with anaphylactic reactions to vaccine should not be reimmunized.

Immune globulin (IG) preparations interfere with the serologic response to live, attenuated virus vaccines. Mumps vaccine should be given during the 2 weeks before or 3 months after receipt of a standard dose of IG or blood transfusions and for longer periods after high-dose immune globulin intravenous (IGIV).

Children with compromised immunity should not receive mumps vaccine. The American Academy of Pediatrics (AAP) does not recommend MMR vaccine for children with most immunodeficiency diseases, including children receiving immunosuppressive therapy (e.g., corticosteroids, alkylating agents, antimetabolites, radiation), those with malignancy who are receiving immunosuppressive therapy, or those who have undergone bone marrow transplantation.[24] Children can receive mumps vaccine if they have not received immunosuppressive therapy for at least 3 months and their underlying disease is in remission. Patients with HIV should receive mumps vaccine as part of the MMR vaccine unless they are severely compromised.[24,136] The second dose of MMR vaccine can be administered as early as 4 weeks after the first dose to induce seroconversion as early as possible. Nonimmune contacts of immunosuppressed people should be immunized because vaccinated people do not transmit attenuated MuV.

Control Measures

The CDC and AAP recommend a 5-day isolation period after onset of parotitis under standard and droplet precautions.[137,138] IG does not offer effective postexposure prophylaxis, and mumps vaccine is not effective in preventing illness after exposure. Mumps outbreaks carry a high economic and resource burden.[139]

In college and university settings, prematriculation MMR completion may prevent the introduction of mumps and limit its spread.[2] During an outbreak, standard control measures include isolation, contact tracing, and catch-up immunization campaigns.[22] Vaccination programs during outbreaks are effective in preventing disease after subsequent exposures.

Data on the effectiveness of administration of a third dose of MMR vaccine to control outbreaks in highly 2-dose vaccinated populations are limited.[15,140] Practitioners should consult their local health department for guidance on the administration of a third dose of MMR in selected high-risk populations.[141] Ring vaccination may be an effective strategy to prevent mumps outbreaks in confined settings.[142]

Key Points

Diagnosis and Management of Mumps Infection

Microbiology

- Negative-sense, single-stranded RNA virus
- Member of *Rubulavirus* genus in the Paramyxoviridae family
- One serotype but at least 12 genotypes based on variability in the *SH* gene

Epidemiology

- Humans are the only known host.
- Virus is spread by respiratory secretions.
- In the prevaccine era, mumps infections were most common during winter and spring in children <10 years of age.
- Incubation period is 12 to 25 days.
- Patients are most contagious 1 to 2 days before and for 5 days after the onset of symptoms.

Clinical Findings

- One or more salivary glands can be swollen.
- In 30% of cases, the patient has only upper respiratory tract infection symptoms.
- Other manifestations of infection include

▪ Meningitis or encephalitis

▪ Orchitis

▪ Thyroiditis

▪ Myocarditis

▪ Sensorineural hearing loss

- Hepatitis
- Arthritis
- Oophoritis
- Glomerulonephritis
- Pancreatitis
- Transverse myelitis
- Thrombocytopenic purpura

Diagnosis

- Virus can be isolated from saliva, throat, urine, and CSF.
- Reverse transcriptase polymerase chain reaction (RT-PCR) is the preferred method for detecting mumps virus RNA in clinical specimens.
- Positive serum mumps IgM antibody result confirms acute infection but can be negative in previously immunized people.
- A fourfold or greater rise in mumps IgG levels between acute and convalescent serum samples also can be used to diagnose infection.

Prevention

- Mumps-containing vaccination at 12–15 months of age with a second dose at 4–6 years of age
- Mumps-containing vaccines are safe and very effective for immunocompetent children.

Isolation

- Hospitalized patients are cared for under standard and droplet precautions for 5 days after onset of symptoms.
- Children in school or childcare should be excluded from attending for 5 days after onset of symptoms.

Respiratory Syncytial Virus

H. Cody Meissner

Respiratory syncytial virus (RSV) is one of the last viral infections that continues to cause annual outbreaks and for which no safe and effective vaccine is available. RSV infects most children at least once in the first 2 years of life. RSV infection in the first 12 months of life is the leading cause of hospitalization, accounting for between 57,000 and 172,000 hospitalizations annually.[1,2] Globally, RSV is estimated to account for as many as 200,000 deaths of children younger than 5 years of age, with a disproportionate number occurring in resource-limited countries.[3,4]

The initial RSV infection induces cellular immunity and neutralizing antibodies. However, immunity is not complete, and RSV reinfections continue to occur throughout life. How RSV avoids or inhibits the immune response to cause reinfection is not well understood.[5] Most primary RSV infections are symptomatic, and most infections involve only the upper respiratory tract. Among the elderly, especially those with comorbidities, RSV is an important cause of morbidity and mortality.[6]

Description of the Pathogen

RSV is an enveloped, nonsegmented, negative-sense RNA virus. Human RSV is classified as a species in the genus *Orthopneumovirus* in the family *Pneumoviridae*.[7] Other members of the Paramyxoviridae family include measles, mumps, parainfluenza, Nipah, and Hendra viruses. The pleomorphic RSV virion contains a helical nucleocapsid surrounded by a viral envelope derived from the plasma membrane of the host cell.

The viral nucleocapsid is composed of viral proteins in complex with the RSV genome, which encodes 11 proteins. The entire RSV genome has been sequenced and consists of more than 15,000 nucleotides. Ten genes are transcribed into 10 separate mRNAs, except the gene for M2 mRNA, which encodes two viral proteins, resulting in a total of 11 distinct viral proteins.[7]

Viral encoded proteins include components of the nucleocapsid and RNA-dependent RNA polymerase complex (i.e., nucleoprotein [N], phosphoprotein [P], large polymerase protein [L], and two regulatory proteins involved in RNA transcription and processing [M2-1 and M2-2]); the matrix (M) protein, which is important for viral structure; and two nonstructural proteins, NS-1 and NS-2, which modulate the host response to infection, including inhibition of interferon induction.

Three transmembrane glycoproteins project as spikes from the lipid envelope. Glycoprotein G is heavily glycosylated, has highly variable domains, and mediates attachment of the virus to the ciliated epithelial cells of the respiratory tract. Glycoprotein F (i.e., fusion protein) mediates viral penetration of the host cell by facilitating fusion of the viral lipid envelope with the plasma membrane of the cell. After protein F binds to a cellular receptor, it undergoes a conformational and antigenic change that enables viral entry, cell-to-cell spread of the virus, and syncytia formation. The viral surface proteins F and G are the primary targets for host neutralizing antibodies. The third surface protein is a small hydrophobic protein (i.e., SH) that is structurally similar to viroporins, proteins that become inserted into the membrane of infected cells, increase membrane permeability, and disrupt the physiologic properties of the cell.[7]

All RSV strains belong to a single serotype. However, sufficient antigenic dimorphism exists in the G glycoprotein to allow assignment of strains to one of two antigenic subgroups, designated A and B, based on cross-neutralization studies. Two highly variable domains in G are separated by a conserved region that may have a role in suppressing the immune response of the host. A and B subtypes are quite divergent and show antigenic relatedness of about 25%. G protein antigenic relatedness between subgroups is only 1% to 7%, whereas the more highly conserved F protein exhibits 50% antigenic relatedness between subgroups.[7]

Molecular epidemiology studies show that viruses of RSV subgroup A and B may circulate simultaneously in the population and that temporally and geographically distinct RSV epidemics are caused by viruses of multiple subgroups and subtypes. The role of subgroup diversity in RSV epidemics and disease severity is not well understood, although some studies suggest that infection with a virus of the heterologous subgroup may be more common after primary infection.

In contrast to the continual antigenic drift of influenza antigens, the surface glycoproteins of RSV are more antigenically stable. Despite strain diversity, accumulation of new mutations that result in antigenic escape is less common with RSV than with influenza. Nonetheless, nucleotide substitutions in the F protein gene's coding region are recognized. RSV isolates that contain mutations in the F protein gene that confer resistance to palivizumab are detected in 5% to 10% of young children receiving monthly palivizumab prophylaxis. These children can experience a breakthrough RSV infection resulting in hospitalization.[8,9]

Epidemiology

RSV causes outbreaks of disease on a worldwide basis. Countries with a temperate climate tend to have seasonal outbreaks that begin in early winter, peak in January or February, and end by early spring[10] (Fig. 225.1). Countries with a tropical climate are more likely to experience disease throughout the year, with peaks occurring during the rainy season.[4] Efforts to relate RSV activity (including onset and end of yearly outbreaks) to climate conditions suggest a complex interaction with latitude, temperature, humidity, and ultraviolet radiation.[11]

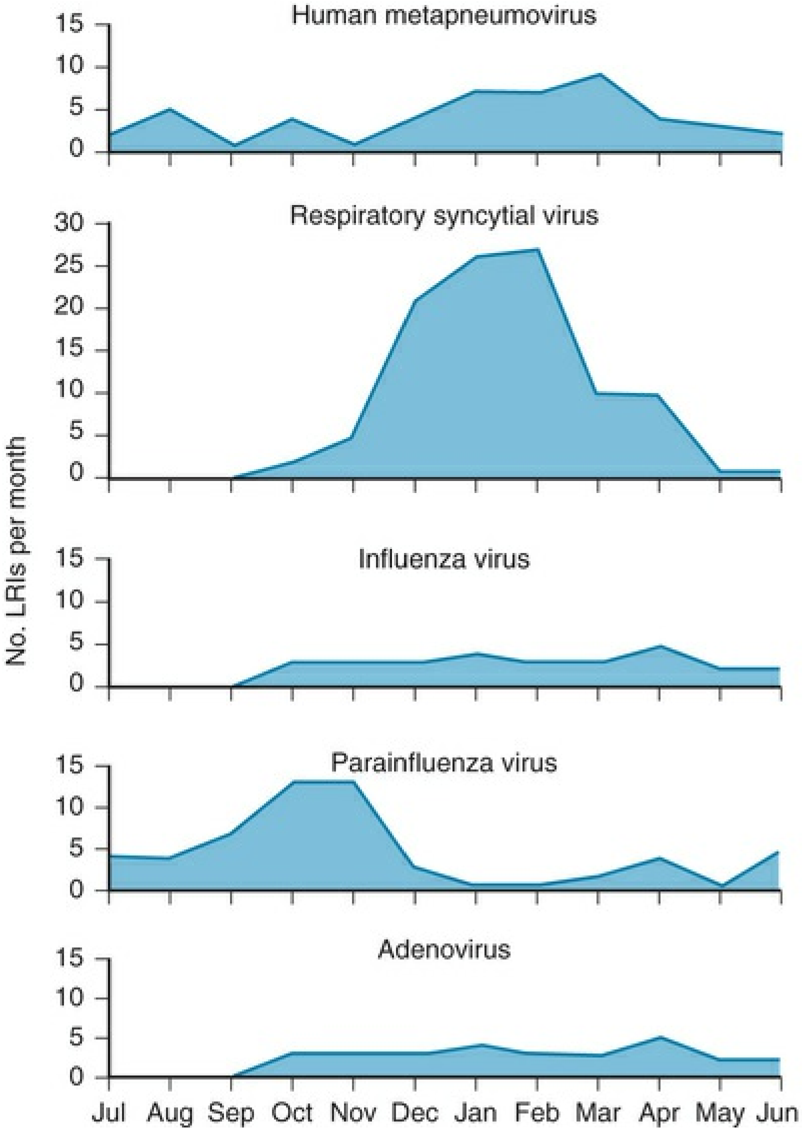

FIGURE 225.1 Epidemiologic pattern of lower respiratory tract illness (LRI) with respiratory syncytial virus and other viruses. (Data from 25 years of surveillance in the Vanderbilt Vaccine Evaluation Clinic.)

RSV is the leading viral pathogen associated with childhood respiratory tract illness requiring hospitalization. RSV hospitalization rates are consistently between 2 and –3 per 100 children younger than 1 year of age in industrialized countries.[1,2] Rates are two to four times higher among infants and young children in certain high-risk groups. During seasonal RSV outbreaks, approximately 75% of children hospitalized for acute lower respiratory tract illness have RSV infection.[1,2,12,13] Fewer than 100 children per year die of RSV-associated complications in the United States.[14] This number is similar to the number of annual pediatric deaths attributable to complications of influenza infection.

RSV is increasingly recognized as an important cause of death of adults and may be associated with 10% of all hospitalizations for pneumonia and 5% of hospitalizations for congestive heart failure among people 65 years of age or older.[6]

Young children at increased risk for severe RSV disease include premature infants (i.e., born before 29 weeks' gestation), infants with chronic lung disease of prematurity or hemodynamically significant congenital heart disease, and patients with an immunodeficiency[1,2,12,15] (Box 225.1). Numerous other factors have been associated with an increased risk of RSV hospitalization, including poverty, malnutrition, exposure to environmental pollutants such as second-hand tobacco smoke, maternal smoking during pregnancy, congenital malformation of the airways, neuromuscular impairment, Down syndrome, decreased cord blood vitamin D concentration, cystic fibrosis, household crowding, childcare attendance, size of the childcare facility, lower level of maternal education, altitude, and lack of breastfeeding.[16,17] However, most of these risk factors are inconsistent from study to study, and in most instances, the impact on increased hospitalization is small (see Box 225.1).

Box 225.1

Medical Conditions Associated With Increased Risk of Severe Respiratory Syncytial Virus Infection

Host factors

- Hemodynamically significant congenital heart disease
- Prematurity defined as <29 weeks' gestation
- Chronic lung disease of prematurity defined as <32 weeks' gestation and requirement for supplemental oxygen for 28 days after birth

Conditions associated with a small increased risk of severe infection

- Malnutrition
- Crowded household
- Childcare attendance

Viable RSV can survive on nonporous surfaces for more than 24 hours. Transmission occurs through contact with contaminated secretions and by large respiratory droplets.[18,19,20] Nasal and conjunctival mucous membrane inoculation are efficient means of transmission. The incubation period is about 5 days, and viral shedding can occur in healthy infants for up to 3 weeks after the onset of illness. Hospital infection control practices that limit RSV transmission include hand hygiene, contact and droplet precautions for patient isolation, use of gowns and gloves, cohorting of infected patients, and use of face masks and goggles.[21]

Rapid diagnosis by antigen or nucleic acid detection assays may enhance hospital infection control by identifying RSV-infected patients. Nonetheless, routine use of viral diagnostic assays is not recommended routinely by the American Academy of Pediatrics practice guidelines.[16,17] Symptomatic patients require isolation regardless of the viral cause.

Healthcare-associated transmission of RSV is an important, preventable cause of RSV disease in hospitalized patients. Failure to adhere strictly to hospital infection control procedures during RSV epidemics and hospital outbreaks can result in fatal healthcare-associated RSV infections.

RSV respiratory tract infection can be complicated by otitis media; other serious bacterial coinfections are uncommon. Antibiotic therapy does not alter the course of uncomplicated RSV bronchiolitis or pneumonia and should be minimized.[16] Routine chest radiography for children with bronchiolitis is not recommended.[16] Many infants with bronchiolitis have radiographic evidence of atelectasis and hyperinflation. When radiographs are obtained for an infant with uncomplicated bronchiolitis, antibiotics are more likely to be administered than when radiographs are not obtained, and there is no difference in outcome.[16]

Pathogenesis and the Immune Response

RSV replicates in cells of the nasopharynx, and infection is confined to the upper respiratory tract in most cases. However, in 30% to 40% of patients, infection spreads to the lower respiratory tract by aspiration of cells containing infectious virus or by cell-to-cell spread, causing bronchiolitis or pneumonia. The immune response induced by RSV may be both protective and pathogenic.[5]

Virus replicates in the ciliated epithelial cells of the mucosa of the bronchioles and pneumocytes of the alveoli, resulting in an inflammatory cell infiltration of the peribronchiolar tissue. Accompanying edema, increased mucus production, and impairment of ciliary action result in various degrees of intraluminal obstruction. Air trapping and hyperinflation result from partial airway obstruction and increased expiratory resistance.[22] Absorption of trapped air in the alveoli distal to the obstruction leads to localized atelectasis and further increases the work of breathing.

Innate and adaptive immune responses participate in viral clearance, although the relative importance of each in the pathogenesis is incompletely understood for primary and recurrent infections. Virus-induced direct cytotoxic injury and an exuberant host inflammatory response contribute to the pathogenesis of bronchiolitis.[23,24]

Young infants are susceptible to severe primary RSV bronchiolitis at an age when maternally acquired RSV-specific antibodies are present, and transplacentally derived RSV antibodies appear to have an ameliorating effect on disease severity. For example, some studies correlate milder RSV illness with higher levels of maternal RSV-specific immunoglobulin G for prematurely born infants. Long-term protection from RSV reinfection is incomplete, although subsequent RSV infections typically are less severe than the initial infection.

Neutralizing antibodies to viral surface glycoproteins are important for reducing the risk of RSV reinfection, and the T-cell–mediated immune response is important for control of established infection and termination of viral replication.[23,24] The roles of innate immunity, adaptive immunity, and toll-like receptors, interferons, surfactants, the inflammatory response, and viral immune evasion in RSV disease are areas of active investigation.

One postmortem study of children who died of acute RSV infection revealed a predominance of macrophages and neutrophils, relative absence of cytotoxic T lymphocytes, and low concentrations of cytokines released by $CD4^+$ and $CD8^+$ lymphocytes.[25] Abundant viral antigen suggests a direct virus-induced cytotoxicity, at least in seronegative infants who experience a primary infection. Other evidence suggests an exuberant host inflammatory response contributes to the pathogenesis of RSV bronchiolitis.

Clinical Manifestations

After an incubation period of 3 to 5 days, RSV-infected infants develop upper respiratory tract symptoms, including rhinorrhea and congestion, sometimes with fever (Box 225.2). Involvement of the lower respiratory tract is associated with nasal flaring, retractions (i.e., supracostal, intercostal, and subcostal), cough, tachypnea, wheezing, and increased work of breathing. Lower respiratory tract disease results in a spectrum of illness severity, ranging from mild disease to life-threatening respiratory failure and cyanosis. The course of bronchiolitis varies and may require serial observations to adequately assess illness acuity. Severe complications, such as a need for intensive care and need for intubation and mechanical ventilation, are uncommon in children with bronchiolitis.

Box 225.2

Common Clinical Manifestations of Respiratory Syncytial Virus Infection

Infancy

Upper respiratory tract infection

Bronchiolitis/pneumonia

Apnea

Older Children and Adults

Upper respiratory tract infection

Bronchitis

Pneumonia (elderly)

Exacerbation of asthma

The ability of the physical examination to predict disease progression is limited.[16] During the first few weeks of life, particularly among preterm infants, infection with RSV may produce minimal respiratory tract signs. Lethargy, irritability, and poor feeding, sometimes accompanied by apneic episodes, may be the presenting manifestations in these infants.

Numerous studies have documented that infants hospitalized with severe viral lower airway disease are more likely to have recurrent episodes of wheezing compared with infants who do not experience severe bronchiolitis. It is not clear whether bronchiolitis results in lung injury that alters normal lung development, predisposing the infant to wheezing, or infants have a preexisting aberration of the immune response or of airway function that predisposes to severe bronchiolitis and recurrent wheezing. Many studies suggest that lung function may be abnormal before the onset of bronchiolitis and that these infants are predisposed to asthma even if bronchiolitis does not develop.[26,27]

Laboratory Diagnosis

RSV can be detected in respiratory tract secretions by virus culture, by antigen detection assays using enzyme immunoassays or direct immunofluorescence assays, and by identification of the virus genome with nucleic acid multiplex assays. Improper specimen collection and handling can impact the performance of any test. RSV is labile, and specimens for virus culture should be kept cold and inoculated into tissue culture as quickly as possible. If virus is present, a characteristic syncytial cytopathic effect can be seen in cell culture within 3 to 7 days. Time to RSV detection in culture can be reduced by the use of shell vial cultures and immunostaining.

Rapid RSV diagnostic tests for antigen detection usually perform well during the peak of the RSV season but have limited usefulness before and after the seasonal peak because of the low predictive value of a positive result. Serologic studies have limited usefulness other than for research purposes.

Nucleic acid detection assays demonstrate viral coinfections in up to 30% of children hospitalized with bronchiolitis.[28] The clinical significance of coinfections is not clear. The results of studies evaluating the relationship between disease severity and viral load have been inconsistent. Results from studies using nuclear amplification techniques suggest that one or more viral pathogens may be isolated from the upper respiratory tract of more than 30% of asymptomatic young children.[29]

Treatment

No available treatment shortens the course of RSV bronchiolitis.[16] Chapter 33 should be consulted for specific guidance on the management of a child with bronchiolitis. Treatment of lower respiratory tract disease includes supplemental oxygen when needed, management of respiratory secretions that may block the upper airways, and maintenance of appropriate hydration. Advances in pediatric critical care are responsible for decreased morbidity and mortality rates attributable to RSV infection.

Ribavirin is a synthetic guanosine nucleoside analogue that inhibits RSV replication and is the only US Food and Drug Administration (FDA) approved antiviral agent for treatment of RSV infection. Aerosolized ribavirin therapy has been shown in small clinical trials of RSV-infected immunocompetent patients to provide a modest improvement in oxygenation, but decreases in mechanical ventilation and duration of hospitalization have not been consistently demonstrated.[30] Considering the conflicting results of clinical trials, high drug cost, cumbersome administration apparatus, and concern about toxicity to healthcare providers, ribavirin usually is not indicated for the treatment of RSV bronchiolitis in immunocompetent patients. The role of ribavirin therapy for the treatment of RSV disease in severely immunocompromised patients such as bone marrow transplant recipients remains controversial.

Prevention

Strict adherence to infection control policies is critical for protection of all patients, especially those who are anatomically and immunologically compromised. Reducing the burden of RSV disease must focus on education regarding the importance of decreasing exposure to and transmission of all respiratory viruses.

Palivizumab is a humanized murine monoclonal antibody produced by recombinant DNA technology. The antibody binds to a conserved epitope on protein F found on RSV subtypes A and B.[23] After intramuscular administration, the antibody is distributed hematogenously throughout the body, including to the lower respiratory tract. When RSV is encountered in the bronchioles, palivizumab binds to protein F and prevents the conformational change that is necessary for the viral lipid envelope to fuse with the plasma membrane. Without fusion, the virus is unable to enter the cell and is unable to replicate.

Palivizumab was licensed by the FDA in 1998, and the American Academy of Pediatrics (AAP) first provided guidance for use of this expensive intervention. Since then, additional information has become available about the small benefit of palivizumab prophylaxis on the risk of hospitalization of preterm infants, the absence of a statistically significant reduction in mortality rates or need for intensive care, the declining incidence of hospitalization for all-cause bronchiolitis, and the absence of reproducible data showing a reduction in subsequent wheezing among palivizumab recipients.[2,31–33]

A randomized, double-blind, placebo-controlled trial of motavizumab, a humanized monoclonal antibody, in healthy, term, Native American infants showed an 87% relative reduction in the hospitalization of those treated for RSV but no difference in the rates of medically attended wheezing in children between the ages of 1 and 3 years.[34] In a prospective, longitudinal birth cohort study of unselected, healthy, term infants in the Netherlands, lung function abnormalities at birth predisposed them to hospitalization for RSV infection and post-RSV wheezing.[35] However, the findings did not support a direct, generalizable causal association with RSV lower respiratory tract infection and subsequent long-term wheezing in term infants.[34]

AAP guidance has become increasingly restrictive based on the data. A summary of current recommendations for palivizumab prophylaxis during the first year of life includes the following groups[17]:

- Infants born before 29 weeks' gestation may receive up to a maximum of five monthly doses. Infants born at or after 29 weeks' gestation do not have a statistically significant greater rate of RSV hospitalization than term infants, and prophylaxis is not recommended.
- Infants with chronic lung disease of prematurity (defined as less than 32 weeks' gestation and a requirement for supplemental oxygen for the first 28 days of life) may benefit from prophylaxis.
- Infants born with hemodynamically significant congenital heart disease may benefit from prophylaxis.

Future Directions

Ultimate control of RSV disease will require development of a safe and effective vaccine. Subunit RSV protein vaccines containing F protein are problematic for use in seronegative infants because of the potential for disease enhancement. However, an RSV protein vaccine may be useful in boosting immunity in nonnaïve, RSV-experienced older children and adults who are at increased risk for severe RSV disease due to underlying disease or advanced age.

Efforts to develop a live, attenuated RSV vaccine have encountered difficulty in providing sufficient attenuation of the vaccine strain so that the vaccine retains immunogenicity but does not cause symptoms in the vaccinee. Additional attenuated vaccine candidates are being developed.[36] A nonreplicating vaccine administered during gestation to boost the maternal neutralizing antibodies that are passed transplacentally to protect the infant during the first few months of life offers particular promise.

Human Metapneumovirus

Jennifer E. Schuster, John V. Williams

Description of Pathogen

Human metapneumovirus (MPV) was first described in 2001 by Dutch investigators who collected a number of unidentified virus isolates over a 20-year period.[1] Electron micrograph and biochemical studies of the virus showed that it was pleomorphic and had a lipid envelope (Fig. 226.1). Reverse transcription polymerase chain reaction (RT-PCR) and sequence analysis of the virus genome identified it as a member of the Pneumovirus subfamily of the Paramyxoviridae family, which includes respiratory syncytial virus (RSV).

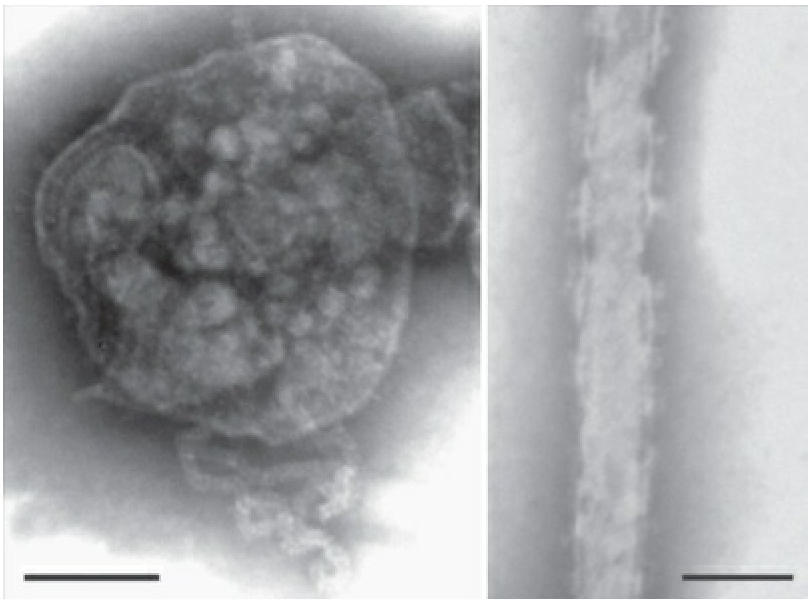

FIGURE 226.1 Electron micrographs of human metapneumovirus. In the whole virion *(left)*, glycoprotein spikes are visible in the viral membrane, and an extruded nucleocapsid is visible below. In the filamentous viral particle *(right)*, a herringbone pattern of the coiled nucleocapsid is visible within the virion. Bar = 100 nm.

MPV is most closely related by sequence homology to avian pneumovirus type C. Avian pneumovirus, discovered in 1979, is a major pathogen of poultry, causing severe respiratory disease in chickens and turkeys with consequent economic losses.[2] Evolutionary genetic analysis suggests that MPV diverged from avian pneumovirus C several hundred years ago.[3–5]

MPV has a negative-sense, single-stranded RNA genome like other paramyxoviruses. The MPV genome encodes nine proteins (Table 226.1 and Fig. 226.2). The fusion (F) protein has domains analogous to those of other paramyxovirus fusion proteins and mediates binding to integrins, internalization, and fusion of the virus and cell membranes.[6–12] Studies using animal models show that F is the major target for neutralizing antibodies.[13–16] The other major MPV membrane protein is G, a heavily glycosylated protein that may serve as an attachment protein for interaction with host cells.[17] In contrast to all other paramyxovirus accessory glycoproteins, the MPV G protein does not appear to be a protective antigen.[15,18,19] The matrix (M) protein augments immune response in candidate vaccines.[20] Analysis of the predicted amino acid sequences of the remaining MPV proteins suggests that they are similar in function to analogous proteins of other paramyxoviruses, although there is little directly conserved sequence.[11]

TABLE 226.1

Genes and Proteins of Human Metapneumovirus

Designation	Nucleotides (mRNA)	Molecular Weight (kd)	Function
N	1200	44	Nucleoprotein; structural protein, replication
P	885	33	Phosphoprotein; structural protein, replication
M	765	28	Matrix; structural protein
F	1620	59	Fusion; binds to integrins, mediates fusion of virus with the host cell membrane; target of neutralizing antibodies
M2-1	564	21	Regulates RNA transcription and replication
M2-2	204	8	Regulates RNA transcription and replication
SH	552	21	Short hydrophobic; function unknown
G	657–714	~75	Glycosylated protein; putative attachment to cells
L	6018	231	Large protein; the RNA polymerase

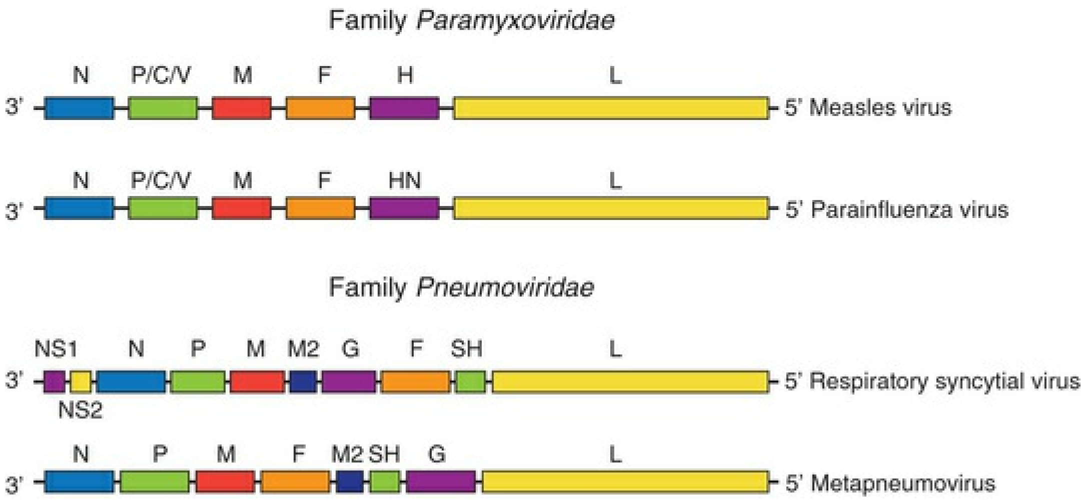

FIGURE 226.2 Schematic of the genomic organization of human metapneumovirus (MPV) compared with other paramyxoviruses. Gene segments are drawn roughly to scale. The MPV genome encodes nine proteins: fusion protein (F), glycosylated protein (G), large polymerase protein (L), matrix protein (M), nucleoprotein (N), phosphoprotein (P), RNA regulator protein (M2), and small hydrophobic protein (SH). H, hemagglutinin; HN, hemagglutinin-neuraminidase;

NS1, nonstructural 1; NS2, nonstructural 2; P/C/V, phosphoprotein.

Phylogenetic analysis of MPV genomes defines two major genetic subgroups of MPV, designated A and B, each with two minor subgroups.[3–5,21] The F protein is highly conserved, with 93% to 95% amino acid identity between major subgroups and about 97% amino acid identity within subgroups. In contrast, the G protein is only 30% to 35% conserved between major subgroups of MPV and 70% within subgroups.[3,21]

Reinfection with homologous or heterologous strains of MPV occurs readily, even during early childhood.[22–24] It is not clear whether the ability of MPV to reinfect humans results from infections with different subgroup viruses that are antigenically distinct, incomplete or waning immunity, or $CD8^+$ T-lymphocyte impairment induced by respiratory virus infections.[25] Longitudinal studies suggest that circulating subgroups alternate over time, indicating some antigenic pressure.[26] Serum neutralizing titers in adults appear to correlate with risk of reinfection.[27] There are no definitive human data determining the degree of cross-protection between different MPV subgroups. However, animal studies of the antigenic diversity between MPV subgroups suggest that there is cross-protective immunity in hamsters and primates.[15,21,28–30] These findings have important implications for the development of vaccines or antibodies against MPV.

There are few data describing the pathogenesis or histologic findings of MPV infection in humans. MPV has been isolated only from the respiratory tract, suggesting that replication is limited to respiratory tract epithelium. One study of lung transplant recipients infected with MPV described acute and organizing lung injury with diffuse alveolar damage, hyaline membrane formation, and cytoplasmic inclusion bodies.[31] Bronchoalveolar lavage fluid from MPV-infected patients contained sloughed, degenerated epithelial cells with eosinophilic cytoplasmic inclusions, multinucleated giant cells, and histiocytes.[32] A major limitation of these reports is that all patients had underlying diseases, and the findings may not reflect MPV infection in otherwise healthy humans.

Detailed analyses of the pathologic features of MPV infection have been described in mice, cotton rats, cynomolgus macaques, and chimpanzees.[33–37] Histopathologic changes included disruption of respiratory epithelium, sloughing of epithelial cells, loss of ciliation, inflammatory infiltrates in the lungs, and abundant fibrin and mucus. Histopathologic changes or evidence of infection were not detected in other tissues. Immunohistochemical staining for MPV in macaques and cotton rats revealed localization of viral antigen almost exclusively at the apical surface of ciliated respiratory epithelial cells.[35,36]

Preliminary studies in humans and animals show that MPV infection stimulates the production of various cytokines and chemokines and invokes T-lymphocyte responses; clearance is unaffected by the absence of natural killer cells.[33,38–43] MPV inhibits type I interferon responses, and because MPV lacks genes associated with this inhibition in other paramyxoviruses, the mechanism is not clear.[44]

Epidemiology

MPV infections occur in annual epidemics during the late winter and early spring months in temperate locations. The MPV season overlaps with those of RSV and influenza viruses, but the peak incidence of MPV usually occurs 1 to 2 months later than the peak of RSV. Prospective surveillance studies conducted over a 25-year period showed that MPV was present in every season, although the prevalence varied from year to year.[22,45]

Different lineages of MPV frequently circulate in a community during the same winter season, although one subgroup may predominate in a given year.[26,45] Viruses from each subgroup appear capable of causing severe lower respiratory tract disease, but different subgroups have not been associated convincingly with different levels of severity of disease.[46,47] In most studies of patients with acute respiratory tract infection, the percentage of MPV detection varies from 6% to 15%. MPV infection usually causes illness; MPV is infrequently detected in nasal specimens from asymptomatic children.[22,48–51]

Studies of hospitalized and outpatient children in many countries have found MPV to be associated with 6% to 40% of acute respiratory illnesses in a given season.[22,45,50,52–83] The average prevalence of infection is 5% to 10%, although it may be much higher during the peak months of MPV circulation. MPV prevalence usually is second to RSV in most studies and is comparable with that of influenza and parainfluenza virus infections.[60,83]

Hospitalization of children for MPV infection occurs primarily in the first year of life, although many studies report that the peak age of hospitalization for MPV is from 6 to 12 months of age and thus later than the peak age of hospitalization for RSV.[56,79,83–92] The biologic reasons for this are unknown. Males appear to be at greater risk of lower respiratory tract infection due to MPV compared with females, similar to sex difference in severity observed for other respiratory viruses. MPV infections are more severe in patients with underlying medical conditions such as asthma, prematurity, cardiopulmonary disease, or immunocompromised states.[50,53,54,69,73,74,93]

MPV infection has been associated with acute respiratory illness in adults. In several studies, MPV accounted for 5% to 15% of all hospitalizations for acute respiratory illness among older patients.[94–96] Most hospitalized adults have chronic underlying conditions such as asthma, chronic obstructive pulmonary disease, or cancer.[69,88–92,95–103] Overall, rates of hospitalization due to MPV infection in adults are similar to those for RSV and influenza infections.[104] The clinical manifestations of MPV infection are slightly different for younger and older patients (Box 226.1).

Box 226.1

Clinical Manifestations of Human Metapneumovirus Infection

Infancy

Bronchiolitis

Pneumonia

Croup

Exacerbation of asthma

Upper respiratory tract infection

Acute otitis media

Older Children and Adults

Upper respiratory tract infection

Croup

Laryngitis

Bronchitis

Asthma exacerbation

Pneumonia (elderly)

Exacerbation of chronic obstructive pulmonary disease (elderly)

Clinical Manifestations

MPV has been associated with a variety of respiratory symptoms and diagnoses (Table 226.2). Children with MPV infection typically have upper respiratory tract symptoms, including rhinorrhea, cough, and fever. Conjunctivitis, vomiting, diarrhea, and rash are reported only occasionally. Lower respiratory tract syndromes most frequently associated with MPV infection are bronchiolitis, croup, pneumonia, and asthma exacerbation. These illnesses are neither clinically nor radiographically distinct from the same clinical syndromes caused by other common respiratory viruses. Central nervous system manifestations rarely accompany MPV infections.[105–107]

TABLE 226.2

Presenting Signs and Symptoms and Diagnoses Associated with Pediatric Metapneumovirus Infection in Eight Clinical Studies[a]

Study Findings	**Boivin et al, 2003**[53]	**Laham et al, 2004**[56]	**van den Hoogen et al, 2003**[50]	**Esper et al, 2004**[54]	**Williams et al, 2004**[22]	**Williams et al, 2006**[45]	**Williams et al, 2010**[60]	**Dollner et al, 2004**[69]

[a] References 50, 53, 54, 56, and 69 include only hospitalized children. Reference 22 includes only children with lower respiratory illness. Reference 45 includes only children with upper respiratory illness.

MPV, metapneumovirus; NA, not applicable; —, not reported; (%), percent of patients in the study.

MPV has been associated with severe and fatal disease, especially in high-risk patients. Colonization with *Streptococcus pneumoniae* has been associated with MPV seroconversion in young children, and limited data suggest that pneumococcal superinfection occurs in some cases.[108–110] A substantial proportion of children infected with MPV develops acute otitis media (AOM), and viral RNA has been detected in middle ear fluid from patients with AOM.[46,83,111–113]

Similar to RSV, transmission of MPV probably occurs by respiratory droplets and secretions. Infectious MPV particles can persist in the environment for hours,[114] and numerous nosocomial outbreaks have been reported.[90,97,100,115–117] The duration of virus shedding in the nasopharynx is 1 to 2 weeks in otherwise healthy children, but it can last for weeks to months in immunocompromised patients.[22,45,50,70,118,119]

Laboratory Findings and Diagnosis

Traditional virus culture techniques are insensitive for the detection of MPV. The virus grows slowly in a limited number of cell types and requires trypsin for replication in culture – conditions that are not used routinely in clinical virology laboratories.[1,114,120–122] There is no commercial rapid antigen test for MPV, although immunofluorescent detection has been reported.

Reliable diagnosis of MPV currently depends on molecular techniques based on nucleic acid amplification assays. Several reverse transcriptase polymerase chain reaction (RT-PCR) methods are quite sensitive.[123–125] Numerous rapid multiplex PCR assays are commercially available that can detect up to 18 or more viruses simultaneously, including MPV.[126,127]

Treatment

Most children infected with MPV can be managed at home with supportive care. For infants and children who require hospitalization, the primary therapies are supplementary oxygen and intravenous hydration. Extracorporeal membrane oxygenation has been used in cases of respiratory failure refractory to mechanical ventilation.[128] Bronchodilators and corticosteroids have been used empirically, but there are no controlled trials of these medications for MPV and no data to support efficacy. Bronchodilator and corticosteroid treatments were effective in a cotton rat model of infection.[129]

Ribavirin and polyclonal human immunoglobulin have virus-inhibiting activity against MPV in vitro equivalent to activity against RSV.[130] However, there are no data supporting the benefits of these therapies beyond anecdotal reports in profoundly immunocompromised MPV-infected patients.[131–136]

Special Considerations

The relationship between MPV and asthma is not clear. MPV infection is associated with exacerbations of asthma in adults and children.[22,51,137–139] Two reports suggest that MPV infection during infancy is associated with asthma or impaired lung function later in life.[140,141] All such studies are complicated by the difficulty of assigning the diagnosis of asthma during infancy, when acute wheezing is frequently associated with viral infections.[104]

In some cohorts, high viral loads have been associated with disease severity.[142,143] Chronic medical conditions, including prematurity, have been associated with severe disease.[144,145] Infections caused by MPV can be fatal in immunocompromised hosts. Several studies suggest that MPV is a common cause of acute respiratory tract infection in children and adults with malignancy or undergoing hematopoietic stem cell transplantation (HSCT), in those with human immunodeficiency virus (HIV) infection, and in lung transplant recipients.[103,132,146–150] One fourth to one half of immunosuppressed patients with MPV infection had a lower respiratory tract infection, and as many as 5% died of pneumonia.[151–153] Mortality rates for MPV infected patients undergoing HSCT are as high as 40%.[154] Long-term prospective studies are needed to characterize fully the extent and severity of disease due to MPV in immunocompromised hosts.

Prevention

The molecular biology cloning technique called *reverse genetics* is used to generate recombinant live paramyxoviruses from DNA copies of virus genomes, allowing the incorporation of specific mutations or entire genes into recombinant viruses.

These techniques have been developed for MPV. Recombinant chimeric bovine/human parainfluenzae virus type 3 and bacille Calmette-Guérin vaccines expressing MPV were immunogenic and protective in small animals.[16,155] Investigators have generated recombinant MPV strains that lack various genes, including the genes that encode the small hydrophobic (SH), G, M2-1, and M2-2 proteins, or that possess avian metapneumovirus gene insertions.[156–159] Many of these recombinant viruses caused attenuated infection in rodents or nonhuman primates but were highly immunogenic, inducing neutralizing antibodies and protection against challenge with wild-type MPV. Virus-like particles are effective at inducing B-cell and T-cell responses in animal models and confer homologous and heterologous genotype protection.[160,161]

MPV-specific monoclonal antibodies similar to palivizumab have shown preventive and therapeutic efficacy in rodent models,[162,163] and some have broadly neutralizing activity against RSV.[164,165] A live, attenuated vaccine has been tested in humans, although only about one third of volunteers developed an antibody response.[166] Several potential vaccine candidates and prophylactic antibodies are in development within 9 years of the discovery of MPV, a remarkable achievement.

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of Human Metapneumovirus

Epidemiology

- Distributed worldwide
- Affects all age groups, but most serious disease is in young children or persons with underlying chronic respiratory diseases or immunosuppression
- Transmission: direct person-to-person contact, droplets, and contact with contaminated environmental surfaces

Clinical Features

- Acute upper and lower respiratory infections
- Disease characterized most frequently by
  - Rhinorrhea, cough, wheezing
  - Associated acute otitis media
- Bronchiolitis, pneumonia, croup, and asthma exacerbation common lower respiratory syndromes
- Hypoxemia is the most common complication in the young and elderly.
- Duration of viral shedding is 1–2 weeks.

Diagnosis

- Detection by nucleic acid testing of respiratory specimens

- Detection by fluorescent antibody testing of respiratory specimens

Treatment

- Supplemental oxygen
- No highly effective antiviral drugs or vaccine available

Rubeola Virus

Measles and Subacute Sclerosing Panencephalitis

Yvonne A. Maldonado, Avinash K. Shetty

Rubeola (i.e., measles) is an acute, highly contagious, vaccine-preventable viral disease of childhood.[1] In the prevaccination era, measles was an almost universal experience during childhood. After the licensure of a live measles vaccine in 1963, the incidence of measles declined markedly in the United States. Because of high rates of 2-dose measles-mumps-rubella (MMR) vaccine coverage, the United States declared elimination of endemic measles in 2000. Recent measles outbreaks due to importations and spread in communities with unvaccinated children highlights the importance of sustaining high levels of population immunity through immunization.[2,3]

Despite substantial progress made in global measles control, large outbreaks continue to occur in many countries due to low rates of vaccine coverage.[4] Measles remains a major cause of child mortality in low- and middle-income countries (LMICs).[5]

Description of the Pathogen

Measles virus (MV) is an enveloped, nonsegmented, negative-strand RNA virus belonging to the *Morbillivirus* genus in the

Paramyxoviridae family. MV is closely related to rinderpest virus, a cattle pathogen that was eradicated in 2011.[6] MV genome consists of 15,894 nucleotides and encodes eight proteins.[7] The surface envelope glycoproteins and the hemagglutinin (H) and fusion (F) proteins are the main targets for development of neutralizing antibodies.[8] The matrix (M) protein is important in virus assembly. The internal proteins, nucleoprotein (NP), polymerase phosphoprotein (P), and large protein (L), form the nucleocapsid. Two nonstructural proteins (C and V) regulate the cellular response to infection.[7]

The receptor binding H protein interacts with F protein and mediates virus attachment and host cell entry. The F protein enhances cell-to-cell spread of the virus. Neutralizing antibodies are primarily directed against the H protein and confer lifelong immunity.[8] There are three identified cellular entry receptors for MV. Human signaling lymphocyte activation molecule (i.e., hSLAM or CD150) is a common immune cell receptor for all MV strains, whereas membrane cofactor protein (i.e., MCP or CD46) is a receptor for vaccine strains.[9] A third receptor, poliovirus receptor–like 4 (i.e., PVRL4 or Nectin 4) is expressed on the adherens junctions of epithelial cells.[10]

Wild-type MV infects only primates. Although MV is a monotypic virus, minor genetic and antigenic variation occurs in some virus strains.[11] These antigenic variations have not compromised long-lasting immunity. MV is inactivated by lipid solvents, heat, and light.

Pathogenesis

Measles is transmitted by direct contact with respiratory droplets or, less commonly by airborne inhalation.[12] The incubation period is about 10 to 14 days from exposure to onset of symptoms. People with measles are contagious from 4 days before to 4 days after rash onset.[13] Measles is highly contagious, with a basic reproductive number (R_0) of 12 to 18.[14] Symptomatic infection develops in 90% of susceptible contacts.

Evidence from studies of nonhuman primates has corrected historically held ideas of pathogenesis.[1] Measles virus initially infects $CD150^+$ alveolar macrophages or dendritic cells, or both, rather than epithelial cells of the upper respiratory tract.[15,16] Infected cells cross the respiratory epithelium and migrate to the draining lymphatic tissue, where the virus preferentially infects CD150$^+$ memory T lymphocytes and B lymphocytes.[17] Infected lymphocytes then spread the virus to respiratory tract epithelial cells through the basolateral surface at later stages of disease by the alternative epithelial cell receptor PVRL4.[10,15]

Pathologic changes associated with viremia include lymphoid hyperplasia of the adenoids, tonsils, lymph nodes, spleen, and intestinal tract. Target infected cells include the epithelial or endothelial cells, B and T lymphocytes, monocytes or macrophages, and dendritic cells.[17,18] Multinucleated giant cells are found most commonly during the early stage of measles in the nasopharynx, tonsils, and bronchial mucosa.[19] Intranuclear inclusions and syncytial epithelial cells may be seen. Mononuclear infiltration with peribronchial inflammation occurs in the respiratory tract.

Immune Response

Adaptive immune responses are important in developing and maintaining lifelong immunity to measles.[18] The onset of rash coincides with development of measles-specific humoral and cellular immune responses and rapid clearance of infectious virus.[18] However, MV RNA can persist in peripheral blood mononuclear cells for several months, despite development of humoral immunity.[20]

Neutralizing antibodies confer lifelong immunity to measles.[21] Measles-specific serum immunoglobulin M (IgM) appears with the onset of rash, followed by a sustained production of measles-specific serum immunoglobulin G (IgG).[18] Neutralizing antibodies to the H and F proteins are necessary for protection.[8,18] People vaccinated with killed virus in whom atypical measles developed after exposure to MV had neutralizing antibodies to H protein but lacked neutralizing antibody to F protein.[22] In contrast, recipients of live, attenuated vaccine demonstrate neutralizing antibody to the H and F proteins and are immune to infection.

Whereas humoral immunity is important in preventing measles, the cellular immune response appears to be important in aborting symptoms during acute infection.[18] Children with agammaglobulinemia fully recover from measles in the absence of a specific antibody response, whereas deficiency in cellular immunity predisposes children and adults to severe or fatal infection.[23] During acute illness, the initial cellular immune response mediated by cytotoxic CD8$^+$ T lymphocytes and activated type 1 CD4$^+$ lymphocytes is important for MV clearance. Production of cytokines such as interferon γ, and interleukin-2 (IL-2) contribute to the generation of a predominant helper T lymphocyte subtype 1 (Th1) response. During recovery, as viral RNA persists, a shift to the Th2 response influenced by IL-4 and IL-10 likely promotes the development of MV-specific antibodies but can suppress Th1 responses and macrophage activation in response to intracellular microbes.[1,18]

A striking feature of the immune response to MV is the induction of transient cellular immunosuppression after infection. Reduced responsiveness to non-MV antigens can last for several weeks to months after acute infection, resulting in increased susceptibility to secondary infections and increased mortality rates.[18,24] Delayed-type hypersensitivity responses, such as reactivity to the tuberculin skin test, are transiently suppressed, and defects in mitogen-induced lymphocyte proliferation are observed in vitro.[25,26] Other abnormalities include lymphopenia, dominant Th2 responses, and T-cell nonresponsiveness.[18] The mechanisms of MV-induced immune suppression remain unclear.[27]

Epidemiology

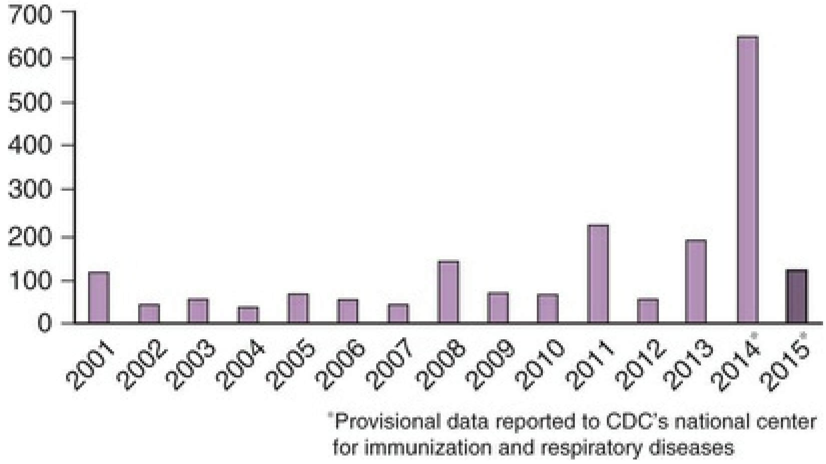
Measles affects only humans; there is no known animal reservoir.[1] The disease is endemic in many regions of the world, with an estimated 20 million cases annually.[28] In the prevaccine era, more than 90% of US children contracted infection by 15 years of age (highest attack rate at 5–9 years of age), and most adults therefore were not susceptible during cyclic epidemics.[29] Epidemics of measles occurred in 2- to 5-year cycles, reflecting the changing pool of susceptible people in the community.[1] In temperate climates, measles epidemics typically occur in late winter through early spring.[1]

In the vaccine era, infants and younger children are most susceptible to measles.[30] Protective transplacental immunity to measles is conferred to infants whose mothers had measles infection or received measles vaccine. Infants whose mothers had measles infection have passive measles antibody for longer periods than infants whose mothers received measles vaccine.[31] The morbidity and mortality rates for measles are highest among infants, immunocompromised (e.g., HIV infection, leukemia), and severely malnourished children, including those with vitamin A deficiency.[32,33] Measles also can be severe in secondary household cases.[34]

Since availability of the measles vaccine in the United States in 1963, a dramatic decline in measles incidence was seen through the 1980s until 1989–1991 period, when about 55,685 cases and 123 deaths were reported.[35] This major resurgence resulted from decreased measles vaccination rates among preschool-aged children, who often resided in crowded, urban areas,[36] and susceptibility of adolescents because of primary vaccine failure (i.e., failure to respond to a first dose).[37] Subsequently, the Advisory Committee on Immunization Practices (ACIP) recommended a second dose of measles-containing vaccine as a combined MMR vaccine.[38]

After high 2-dose vaccine coverage, reported measles cases declined rapidly to 309 cases in 1995.[35] In 2000, the United States declared elimination of endemic measles (i.e., absence of year-round transmission).[39,40] However, imported cases and limited spread occur each year. During the postelimination period (2001–2011), a total of 911 measles cases were reported (median, 61 cases/year; range, 37–220 cases), with a low annual population incidence (<1 case per million people).[41,42] There were about 33 importations/year and 4 outbreaks/year (range, 2–16 outbreaks); 25% of cases were hospitalized.[41,42]

In recent years, a slow but steady rise in measles cases (i.e., 140 in 2008, 220 in 2011, and 189 in 2013) have been reported to the Centers for Disease Control and Prevention (CDC), including a dramatic rise in 2014 (Fig. 227.1).[43,44] Reported cases originated predominantly from large outbreaks in Western Europe, Pakistan, Vietnam, and the Philippines.[43] During 2014, the United States had 668 measles cases reported from 27 states, including 23 outbreaks, representing the greatest number of measles cases since 1994.[44] One outbreak of 383 cases occurred in Ohio, primarily among unimmunized Amish missionaries returning from the Philippines, which experienced a large outbreak in 2014.[44]



*Provisional data reported to CDC's national center for immunization and respiratory diseases

FIGURE 227.1 Measles cases, by year—United States, 2001 to 2015. (Data from Centers for Disease Control and Prevention. Update: measles—United States, January-July 2008. MMWR 2008;57:893-896; Centers for Disease Control and Prevention. Measles (Rubeola). https://www.cdc.gov/measles/cases-outbreaks.html.)

Between January 4 and April 2, 2015, 159 measles cases (age range, 6 weeks–70 years) from 18 states and the District of Columbia were reported to the CDC; 16% of patients were younger than 12 months of age, and 14% required hospitalization. A total of 111 (70%) of these cases were associated with a 2014 multistate outbreak that began in a Disney theme park in California.[3,44,45] Of the 159 cases, more than 80% of cases were unvaccinated or had unknown vaccination status; 96% were import associated. Common sources of importations include unvaccinated US residents or travelers returning from abroad, with subsequent transmission among clusters of intentionally unvaccinated people[2,44–46] (Fig. 227.2). Measles outbreaks carry a substantial economic burden.[14]

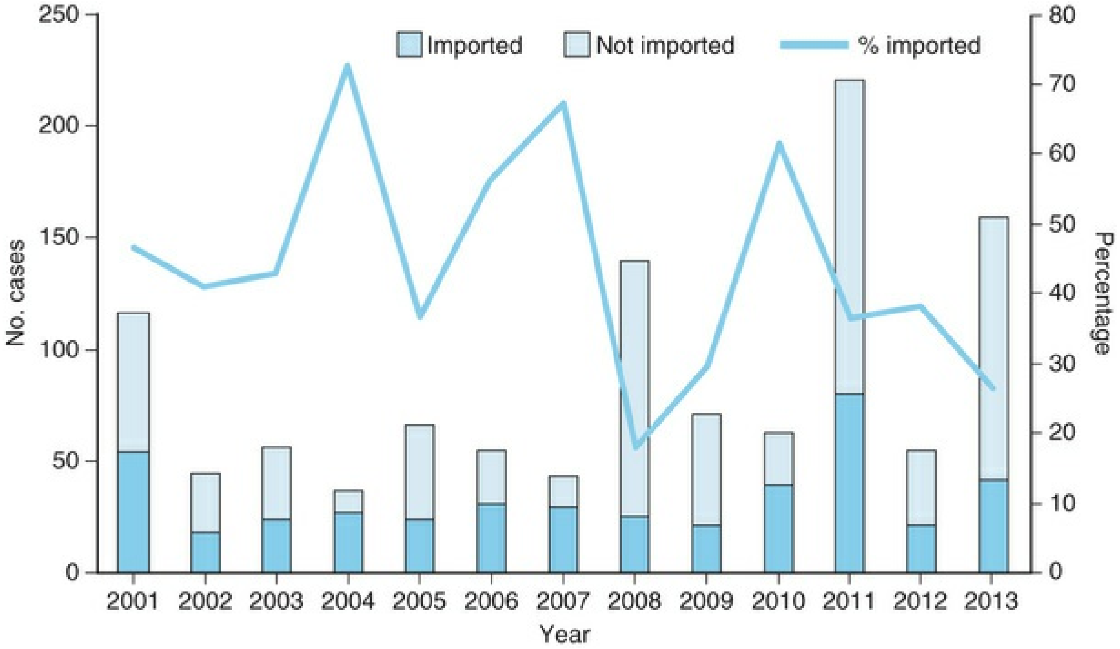


FIGURE 227.2 Measles cases (number and percent) that were directly imported and not directly imported in the United States for 2001 through 2013. Directly imported cases are infections occurring in patients who acquired measles outside the United States and brought the infection into the country. Cases not directly imported include infections that were acquired in the United States but linked to directly imported cases, imported virus, and cases with unknown sources. The 2013 data are for January 1 to August 24. (From Gastañaduy PA, Redd SB, Fiebelkorn AP, et al. Measles—United States, January 1–May 23, 2014. MMWR Morb Mortal Wkly Rep 2014;63:496–499.)

Given the high level of contagiousness, measles outbreaks can occur in communities where less than 10% are susceptible.[47] The growing number of parents hesitant to vaccinate their children is a major concern.[14] In the 2014–2015 outbreak, MMR vaccination rates in the community fell below the necessary threshold to sustain community immunity, resulting in spread to secondary cases.[48] Immunization rates of 96% to 99% are needed to maintain herd immunity and prevent outbreaks.[49]

Substantial progress has been made in global measles control and elimination.[50,51] In 1980, before widespread vaccination, measles accounted for an estimated 2.6 million deaths annually.[52] With improved measles-control strategies, estimated measles deaths worldwide decreased by 75%, from 544,200 in 2000 to 145,700 in

2013.[28] During the 2000–2013 period, measles vaccination prevented an estimated 15.6 million deaths, and there was a 72% decline in the annual reported measles incidence from 146 to 40 cases per million people. The reduction in childhood deaths from measles has accounted for an estimated 23% reduction in the all-cause mortality rate for children younger than 5 years of age.[53]

Measles was eliminated from the World Health Organization (WHO) Region of the Americas in 2002.[54] Elimination of measles is defined as absence of endemic transmission of MV in a defined geographic area for more than 12 months in the setting of a well-performing surveillance system.[55] The WHO Global Vaccine Action Plan has established measles elimination targets in at least five WHO regions by 2020.[56] However, the disease remains endemic in Europe, Asia, Africa, and the Middle East (Fig. 227.3).[57] Large outbreaks have involved broad age groups, including adults.[4,51] Importations of measles into the United States continue to occur, resulting in secondary cases and outbreaks.[2,3,58,59]

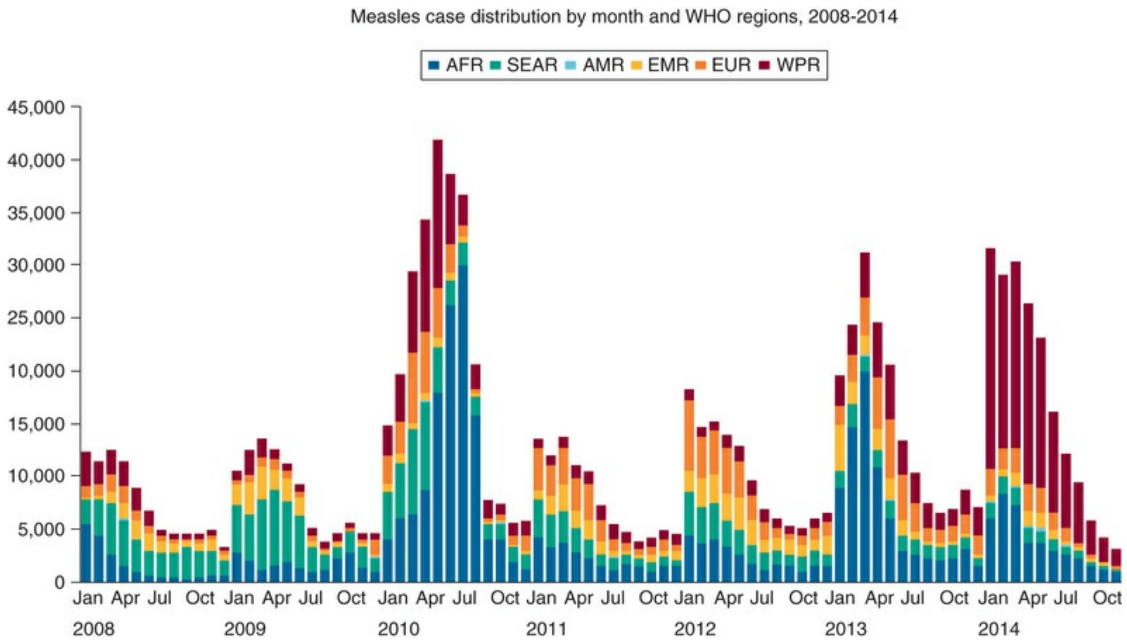

FIGURE 227.3 Measles cases reported to the World Health Organization for September 2014 through February 2015. (From World Health Organization. Measles Surveillance Data. http://www.who.int/immunization/monitoring_surveillance/burden/vpd/surveillance_type/active/mea

Measles eradication is biologically, programmatically, and operationally feasible, and it is cost-effective.[50,60–62] A 2-dose measles-containing vaccine schedule protects most immunocompetent children.[63] Challenges for global measles eradication include weak or conflict-affected health systems, inadequate surveillance of immunization campaigns, vaccine skepticism, and cultural and financial barriers.[51,60–62]

Clinical Manifestations

Typical Measles

After an 8- to 12-day incubation period, a prodromal illness characterized by fever, cough, nonpurulent conjunctivitis, and coryza develops.[1] During the 2- to 4-day prodrome, a pathognomonic enanthem called *Koplik spots*, which are bluish white, 1-mm lesions on a red base, may be visible on the buccal mucosa.[64,65] Koplik spots initially are discrete and appear anywhere on the buccal mucosa, including the hard and soft palate, but they characteristically are located opposite the lower premolars. Lesions eventually coalesce and spread rapidly throughout the buccal mucosa. After the enanthem is seen for 12 to 72 hours, it starts to slough with the appearance of the rash.

The rash typically begins at the peak of the respiratory symptoms, typically about 14 days after exposure and 2 to 3 days after appearance of the Koplik spots. The rash is erythematous and initially maculopapular, starts on the forehead or posterior occipital area, and spreads within 3 days to the trunk and extremities (Fig. 227.4). The rash is more likely to be confluent over the head and upper extremities than over the trunk and lower extremities (Fig. 227.5). The rash usually lasts for 3 to 5 days and fades from red to copper to brown in a cephalocaudal direction; fine desquamation follows. In malnourished children, a deeply pigmented rash with more extensive desquamation may occur.[1,66] The rash can become mildly hemorrhagic, and petechiae or purpura occasionally occurs.[67]

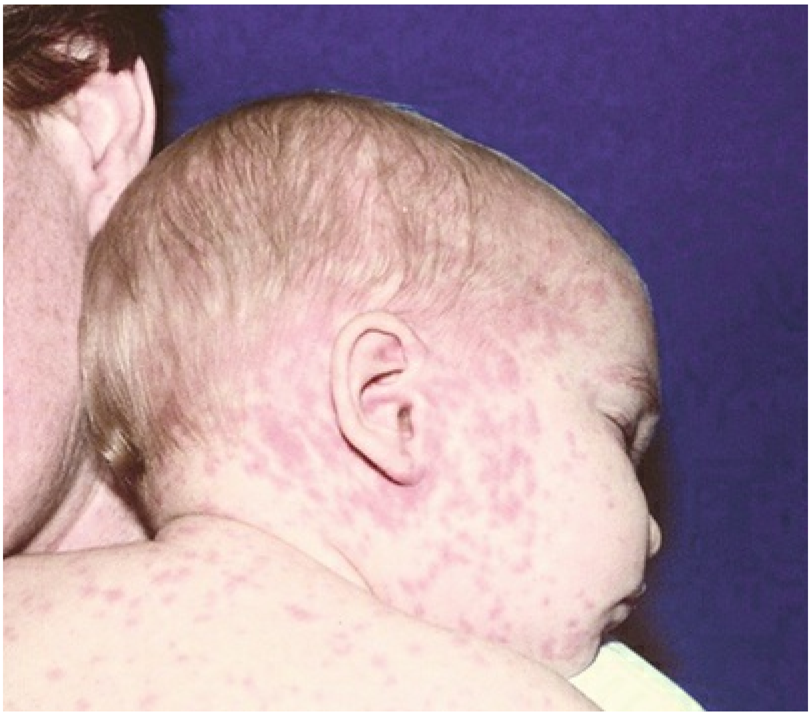

FIGURE 227.5 Measles rash on day 5, showing the typical confluence and density of lesions on the head and scattered lesions on the trunk. (Courtesy of J.H. Briené.)

Symptoms during the exanthematous phase include high fever (up to 40°C) that peaks 2 to 3 days after rash onset, continued respiratory symptoms, nonpurulent conjunctivitis, pharyngitis, and mild generalized lymphadenopathy. After the fever peaks, it usually resolves rapidly, followed by clinical recovery in uncomplicated measles. Persistent fever is a possible indication of secondary bacterial infection. Occasionally, diarrhea, vomiting, and abdominal pain may occur. In LMICs, diarrhea is a major complication of measles.[68]

Transient anicteric hepatitis has been reported in young adults with measles.[69] An atypical form of measles occurred in people infected with wild-type MV who had previously received formalin-inactivated (i.e., killed) measles vaccine in the United States between 1963 and 1968.[70] A severe disease that lacked many typical features of measles had a nonconfluent, caudocephalad progression of rash, which sometimes had a petechial and vesicular component. Pneumonia, hilar adenopathy, pleural effusion, and prolonged recovery (≥2 weeks) were common.

Hemorrhagic Measles

Severe hemorrhagic measles (i.e., black measles) is most common among infants in developing countries and is characterized by a sudden onset of high fever accompanied by seizures or altered mental status.[67] Other manifestations include pneumonia; an extensive hemorrhagic exanthem and enanthem; bleeding from the mouth, nose, and gastrointestinal tract; and disseminated intravascular coagulation. The prognosis is poor, and fatalities are common.[67]

Modified Measles

Modified measles is an attenuated form of infection that can occur in people who have received immune globulin after exposure to measles.[65] The clinical manifestations of modified measles are milder than those of typical infection, and the incubation period is prolonged (14–20 days). Complications are rare.

Laboratory Findings and Diagnosis

Laboratory abnormalities include leukopenia and lymphopenia.

The diagnosis of measles is confirmed by serology, virus isolation, or detection of measles virus RNA by reverse transcriptase polymerase chain reaction (RT-PCR) on clinical samples.[71] Serology (often by enzyme immunoassay) is the most widely used method to confirm the diagnosis.[72] A presumptive diagnosis can be made by detection of MV-specific immunoglobulin M (IgM) antibody on a single serum sample.[13] A fourfold or greater rise in the IgG antibody titer from paired acute and convalescent sera obtained at least 10 days apart also indicates recent infection.[13]

MV-specific IgM antibody usually is detectable 1 to 2 days after rash onset and persists for 30 to 60 days in unimmunized people.[73] The timing of specimen collection, vaccination history, and the type of assay can influence the sensitivity of measles IgM assays. False-negative IgM results occur for less than 20% of patients during the first 72 hours after rash onset; repeat testing is recommended if the generalized rash persists for more than 72 hours.[13,74] IgM antibody can be present transiently or absent in infected people who previously received 1 or 2 doses of measles vaccine. MV-specific IgM antibody testing therefore is not recommended to exclude measles infection in vaccinated people.[13]

In the United States and other countries with high MMR vaccine coverage, serology and RT-PCR assay are recommended to confirm the diagnosis.[13,71] Specimens from the throat or nasopharynx are preferred for RT-PCR assay, and sampling more than one site may increase detection.[13] MV sometimes can be isolated from blood, urine, and secretions of the throat and nasopharynx, but isolation is difficult and not recommended routinely.[13] MV genotyping may be beneficial for differentiating wild-type from vaccine virus strains and performing molecular epidemiologic studies to identify sources and transmission patterns of imported disease.[75,76]

In LMICs with a low incidence of measles, clinical diagnosis may be difficult.[1] The differential diagnosis of measles includes rubella, enteroviral infection, exanthem subitum, adenovirus, Epstein-Barr virus, parvovirus, and streptococcal or staphylococcal infections. Drug hypersensitivity, Rocky Mountain spotted fever, dengue, leptospirosis, and Kawasaki disease also can be confused with measles.

Treatment

No specific antiviral therapy is indicated for measles. Ribavirin is active against MV in vitro and has been used to treat immunocompromised patients with measles pneumonia and encephalitis.[77–79] Ribavirin has not been evaluated in controlled clinical trials and is not licensed for the treatment of measles.

In LMICs, administration of vitamin A to children with active measles decreases morbidity and mortality.[80,81] US studies have correlated low vitamin A levels in younger children with measles with increased morbidity rates.[82,83] The WHO recommends vitamin A administration to all children with measles.[84] The CDC also recommends vitamin A administration to all children with severe measles (e.g., hospitalized patients).[13,85] Vitamin A treatment for measles is administered once daily for 2 consecutive days as follows: 50,000 IU orally for infants younger than 6 months of age; 100,000 IU orally for infants between 6 and 11 months of age; and 200,000 IU orally for children aged 12 months of age or older. For children with clinical evidence of vitamin A deficiency, a third dose should be administered 2 to 4 weeks later.[1,86]

Special Considerations and Complications

Respiratory Tract Complications

Based on 1985–1992 US surveillance data, one or more complications occurs in about 30% of reported measles cases, and deaths were reported in about 0.2% of cases.[87] Children younger than 5 years of age, immunocompromised children, and malnourished children are at highest risk for adverse outcomes. Respiratory tract complications are common and reflect the intense inflammatory response to MV replication and disruptions of the epithelial cell integrity, possibly compounded by immunosuppression.[18,24,65,88]

The most common complication of childhood measles is acute otitis media (7% to 9%). Respiratory complications include bronchopneumonia, bronchiolitis, laryngotracheobronchitis, and pneumonia.[1,65,89,90] Pneumonia due to MV or secondary bacterial superinfection occurs in 1% to 6% of children with measles and accounts for 60% of deaths. Diarrhea occurs in about 8% of cases.[87] Rare complications include thrombocytopenic purpura, hepatitis, appendicitis, ileocolitis, pericarditis, myocarditis, glomerulonephritis, hypocalcemia, severe desquamation, and myositis.[65]

In LMICs, the case-fatality rate is 2% to 15%, compared with an estimated 0.2% to 0.3% in the United States.[91,92] Pneumonia and diarrhea are the most common life-threatening complications of measles, especially in malnourished children, and pneumonia accounts for 56% to 86% of measles-related deaths.[93] The most common secondary bacterial pathogens causing pneumonia are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenza*.[91] Keratoconjunctivitis is a common complication after measles, especially in children with vitamin A deficiency, and it can result in blindness.[94]

Central Nervous System Complications

Central nervous system (CNS) complications of measles include acute encephalitis, subacute sclerosing panencephalitis (SSPE), and measles inclusion body encephalitis in immunocompromised hosts.[95–97]

Acute Encephalitis.

Acute encephalitis occurs in about 1 of 1000 measles cases and affects primarily older children and adults.[87,98] Fever, headache, altered mental status, seizures, and multifocal neurologic signs usually occur 6 days (range, 1–15 days) after appearance of the rash. Cerebrospinal fluid (CSF) shows mild to moderate lymphocytic pleocytosis, elevated protein levels, and normal glucose concentrations.[98]

The pathogenesis of measles encephalitis is ill defined, but it probably represents an autoimmune disorder,[99] although MV has been isolated from the CNS in some patients.[100] Neuropathology is characterized by perivenular inflammation, demyelination, and gliosis. Magnetic resonance imaging (MRI) findings may be compatible with acute disseminated encephalomyelitis. The case-fatality rate for primary measles encephalitis is about 15%; about one fourth of survivors have long-term sequelae such as seizures and mental retardation.[95,98]

Subacute Sclerosing Panencephalitis.

SSPE is a rare chronic complication of measles characterized by a slowly progressive, fatal neurologic disease due to persistent CNS infection.[101] The incidence of SSPE in the prevaccine era was 1 in 100,000 measles cases.[87] The disease is rare in the United States since universal measles vaccination was initiated.[102,103]

SSPE typically is associated with the acquisition of measles before age 2 years.[102] Travel of infants to measles-endemic countries before receipt of vaccine can be a clue to SSPE. The disease is two to three times more common among males, with onset usually occurring 7 to 10 years after asymptomatic, mild, or typical measles.[95]

Brain histopathology in SSPE cases demonstrates panencephalitis with lymphocytic and plasma cell infiltrate, demyelination, neuronal loss, and type A and type B intranuclear Cowdry inclusion bodies.[104] Electron microscopy of the inclusion bodies reveals paramyxovirus-like structures.

The pathogenesis of SSPE is unclear. An abnormal immune response to MV and the presence of defective or mutant MV strains in the brain may be important.[101] Although patients with SSPE have high CSF and serum measles antibody concentrations, cellular immune responses are limited. Defective MV strains can produce incomplete CNS infection and remain latent in host cells.[101,105] MV mutants possessing the fusion protein with enhanced fusion activity may promote neuronal cell entry and spread.[106]

Early symptoms of SSPE include subtle mood disturbances, hyperactivity, and cognitive decline. As the disease progresses, myoclonic seizures, motor disturbances, and ocular disease (necrotizing retinitis in 50%) may occur. Eventually, coma, autonomic instability, akinetic mutism, and vegetative state supervene. Death usually occurs within 1 to 3 years after symptom onset.[95]

The characteristic electroencephalographic (EEG) finding is a burst-suppression pattern with paroxysmal high-amplitude bursts and background suppression. Typical CSF findings include marked elevations in MV antibody titers (range, 1 : 8–1 : 64 or higher) and positive CSF oligoclonal bands. Serum MV antibody levels also are markedly elevated (>1 : 1280). Computed tomography demonstrates cortical brain atrophy. MRI findings for one patient are shown in Fig. 227.6. Brain biopsy is diagnostic, although the triad of clinical criteria, characteristic EEG pattern, and elevated CSF measles oligoclonal bands is sufficient to make the diagnosis.[101]

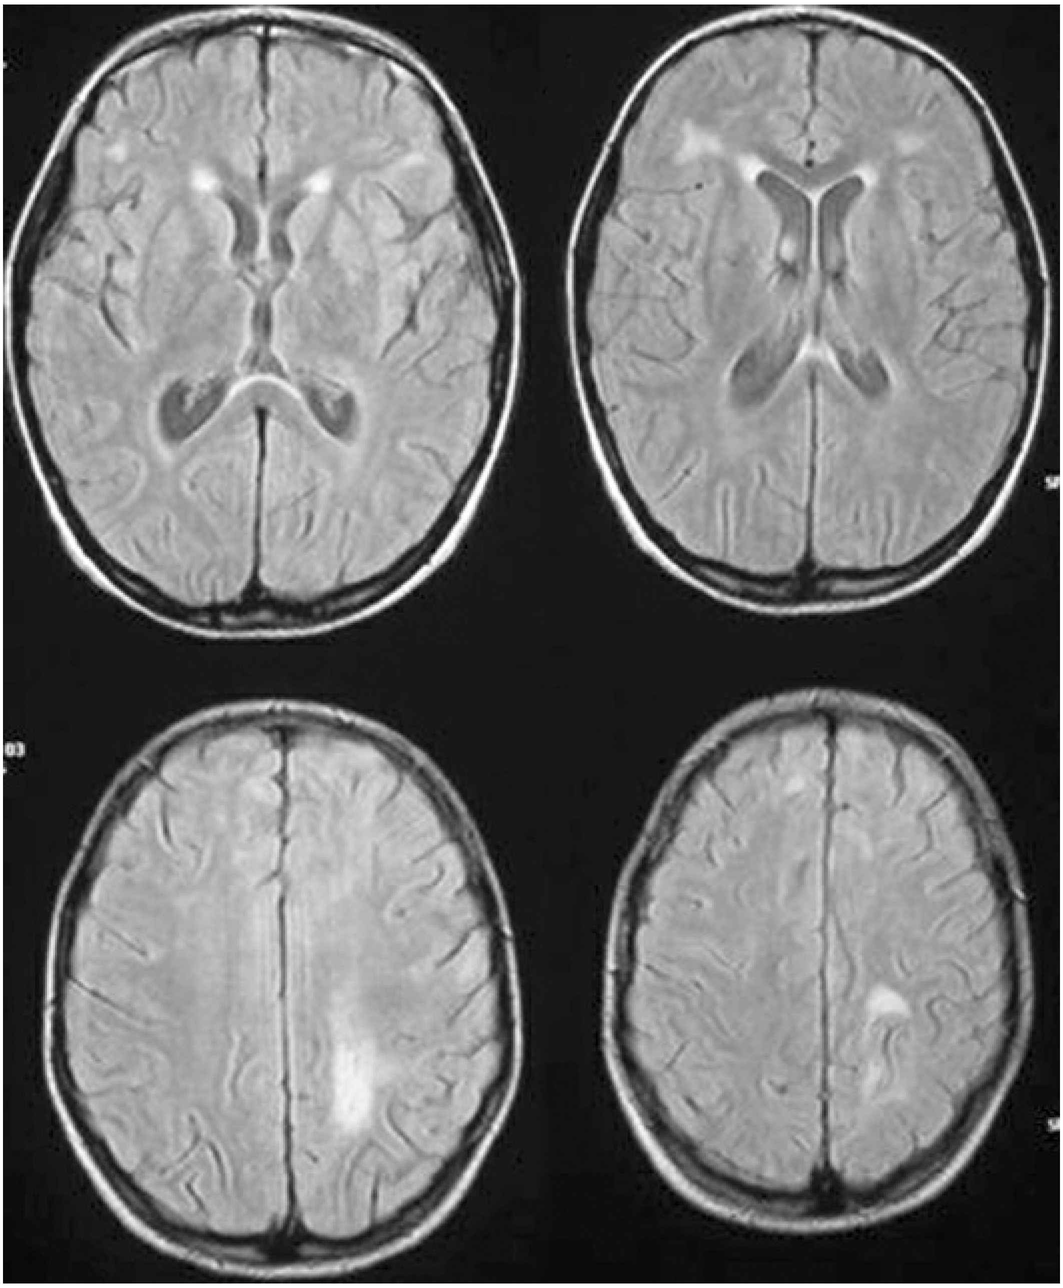

FIGURE 227.6 In 2006, an 8-year-old girl had clumsiness and decreased school performance that progressed over 13 weeks to weakness of the right face and extremities, hyperreflexia, jerking movements, decreased intellectual capacity and alertness, seizures, and death. Initially diagnosed and

treated as acute disseminated encephalomyelitis, evaluation of the clinical course and electroencephalogram showing slowing with burst suppression led to consideration of subacute sclerosing panencephalitis. The measles indirect fluorescent antibody titer was 1: 8192 in serum and 1: 512 in cerebrospinal fluid. The patient had visited Turkey from age 7 to 10 months and had a 1-day febrile exanthematous illness. Axial fluid-attenuated inversion recovery (FLAIR) magnetic resonance images show brain atrophy and white matter lesions in the frontal (bilateral), parietal, and temporal lobes. (Courtesy of E.N. Faerber, J.J. Melvin, and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Therapy with corticosteroids, plasmapheresis, ribavirin, inosiplex, and immunomodulating therapy (e.g., intrathecal interferon α and β) have been used, but the responses have been poor.[107–109]

Measles in Immunocompromised Hosts

Primary viral pneumonia (i.e., giant cell pneumonia) and encephalitis are common in malnourished or immunosuppressed children with deficient cellular immunity (e.g., congenital immunodeficiency, receipt of chemotherapy for cancer, HIV infection).[23,110–115] Clinical diagnosis can be challenging because the typical rash may be absent.[110] MV can be isolated persistently from blood and the nasopharynx for up to 1 month after rash onset. The antibody response can be limited.

Death usually results from progressive pneumonia. In one study, the case-fatality rate for immunosuppressed patients with measles was 70% for cancer and 30% for HIV-infected patients. HIV-infected patients who had received measles vaccine had lower mortality rates than unvaccinated patients.[112]

Subacute measles inclusion body encephalitis in an immunocompromised host (typically with lymphoblastic leukemia) develops within 1 year after acute infection or vaccination.[95,97] Symptoms include seizures, altered level of consciousness, hemiparesis, hemiplegia, ataxia, aphasia, slurred speech, and visual effects. Fever usually is absent, and CSF findings typically are normal, although mild pleocytosis and elevated protein levels may be seen.[114] The EEG pattern shows nonspecific abnormalities, and neuroimaging is normal at presentation. Detection of MV RNA by brain biopsy is the only reliable method of diagnosing subacute measles encephalitis.[95]

The mortality rate is high, especially for those with T-lymphocyte deficiencies.[95] Anecdotal benefit with ribavirin therapy has been reported.[115]

Measles in pregnancy can be a serious disease, with the potential for complications, especially pneumonia resulting in fatal outcomes.[116] Data on the effect of measles on the outcome of pregnancy are limited, and reports of congenital measles are sporadic. Infants born to mothers who acquire measles late in pregnancy can develop a measles exanthem within the first 10 days of life. No distinct congenital measles syndrome has been described, but the severity of the systemic illness in pregnant women with measles infection can cause spontaneous abortion, premature labor, and low birth weight babies.[116,117]

Prevention

Active Immunization

Active immunization with measles-containing vaccine is the best method of preventing measles.[63,118] The isolation of MV in tissue culture by John Enders led to the development of the first live, attenuated measles vaccine, which was licensed in 1963 in the United States.[119] The more attenuated Moraten strain of live, attenuated measles is the exclusive measles vaccine currently licensed for use in the United States. The vaccine is prepared in chick embryo cell culture and produces a mild, noncommunicable infection. Measles vaccine is available in the United States only in combination form as MMR and measles-mumps-rubella-varicella (MMRV) vaccines.

Interference by transplacentally transferred passive antibodies against measles is the most important obstacle to early infant measles immunization. The optimal age of first immunization can vary from 6 to 15 months, depending on the country of residence and risk of acquiring measles.[1,61] In the United States, measles vaccines were given at 9 months of age until 1965, at 12 months between 1965 and 1976, at 15 months between 1977 and 1994, and at 12 through 15 months thereafter.[120] The increasing age at vaccination was based on low seroconversion rates in infants vaccinated when younger than 12 months of age. Increasing vaccine failure rates of up to 95% with decreasing age at vaccination below 12 months of age have been observed, and several studies have confirmed a correlation between vaccine failure with young age and high maternal measles antibody titer.[121,122] Measles vaccine efficacy rates of 95% are reported in populations that received vaccine when older than 12 months of age.[123]

Vaccine-induced immunity, now the case in most US women of reproductive age, is associated with low measles-specific antibody titers and lower titers and shorter duration of passive antibodies in offspring.[124–126] Most infants lose maternal antibody by 9 to 12 months of age.[124] An earlier loss of maternal antibodies against measles can result in increased susceptibility of infants younger than 12 months of age to infection.[31] Measles-specific T-lymphocyte immunity is induced after early measles vaccination despite the presence of antibody, and it may prime a balanced humoral and cellular response.[127] T-lymphocyte immunity can persist after early vaccination.[128] All infants older than 6 months of age who travel outside of the contiguous United States should be given MMR, which is repeated as a first valid dose at 12 to 15 months of age.[13]

Measles antibodies develop in about 85% of children vaccinated at age 9 months, 95% of those vaccinated at 12 months, and 98% of those vaccinated at 15 months.[1] The ACIP and the American Academy of Pediatrics (AAP) recommend the first dose of measles vaccination at 12 through 15 months of age and a second dose at 4 through 6 years of age before school entry.[13,63] The second dose is intended to provide immunity to children who have primary vaccine failure (≤5%) after the first dose.[42] The currently available measles vaccine is highly effective, with one dose. It is about 95% protective in children receiving the vaccine at 12 months of age or earlier; two doses provide more than 99% protection when administered at least 4 weeks apart.[63,118] All school children who have not received the 2-dose MMR vaccine must receive catch-up vaccination, including at the 11- to 12-year-old visit and beyond.[13]

Vaccine-induced immunity can last several decades or longer in healthy people.[129] Secondary vaccine failure is infrequent (~5%) at 10 to 15 years after vaccination, but it is likely lower when the age of first vaccination is 12 months or older.[130] Although antibody concentrations can wane, protective immunity may still be retained. A secondary immune response, typically not associated with symptoms, often occurs after re-exposure to MV, with a marked increase in antibody concentrations.[1]

Infants between the ages of 6 and 11 months should receive 1 dose of MMR vaccine during community-wide outbreaks or before travel to countries where measles is endemic or in epidemic situations; however, 2 subsequent valid doses should be given at 12 months of age or later.[13] Children 12 months of age or older should receive 2 doses of MMR vaccine before international travel that are separated by at least 28 days.[63]

Use of MMRV vaccine is recommended for children between the ages of 12 months and 12 years.[131] In two postlicensure studies, one additional febrile seizure per 2300 to 2600 children between the ages of 12 and 23 months was observed in those who had received MMRV compared with those who received MMR vaccine and V vaccine administered as separate injections at the same visit.[132,133] There was no increased risk of febrile seizures associated with the second dose of MMRV at 4 to 6 years of age.

Based on these data, the ACIP and AAP recommend the administration of MMR and V vaccine as two injections at a single visit at 12 to 47 months of age, unless the parent or caregiver expresses a preference for the MMRV vaccine. Use of the MMRV vaccine usually is preferred over separate injections for the second dose of measles, mumps, rubella, and varicella vaccines at any age (i.e., 15 months to 12 years) and for the first dose at 48 months of age or later.[131]

MMR vaccine is not recommended for pregnant women.[13] Measles vaccine is contraindicated in immunosuppressed children, except for asymptomatic HIV-infected children, who are at risk of severe or fatal disease after measles. HIV-infected children without severe immunodeficiency and their susceptible household contacts who themselves are not severely immunocompromised should receive the MMR vaccine, although primary vaccine failure is common in HIV-infected children.[110,134]

The available measles vaccines are safe in immunocompetent people. Adverse reactions to the MMR vaccine may include fever (<15%) and transient rash (5%) in recipients. Febrile reactions usually occur 7 to 12 days after vaccination and persist for 1 to 2 days.[63] Encephalitis after MMR vaccination is rare (<1 case/1 million doses). Allergic reactions related to allergies to egg or egg products or to neomycin are uncommon. Patients with a history of nonanaphylactic egg allergies or contact dermatitis from neomycin may receive measles vaccine. Those with a hypersensitivity reaction after the first dose should be tested for measles immunity, and if found to be nonimmune, they may require skin testing and desensitization before receiving the second dose of measles vaccine.[13] Vaccination is contraindicated for people with a history of immediate anaphylactic reactions to previous vaccine dose.[13] Hypothesized associations between measles vaccination and the development of Crohn disease, other inflammatory bowel diseases, and autism have not been supported by several rigorous studies.[135–137]

In countries with a high measles incidence, the WHO recommends routine measles vaccination at 9 months of age.[1] The second vaccine dose usually is administered in primary healthcare systems or during mass immunization campaigns. Efforts are ongoing to develop an ideal measles vaccine, which would be inexpensive, safe, immunogenic in young infants, heat stable, and be given as a single dose by needle-free administration.[1] Innovative approaches such as aerosolized measles vaccine measles could contribute to elimination efforts worldwide.[138,139] However, in a randomized, controlled trial published in 2015, the aerosolized measles vaccine was inferior to the subcutaneous vaccine, resulting in lower rates of seropositivity.[140] The WHO strategy for global elimination of measles is focused on achieving and maintaining high coverage with the 2-dose MMR vaccine coupled with effective laboratory-based surveillance.[141]

Passive Protection

Human immune globulin (IG) given intramuscularly (IGIM) or intravenously (IGIV) within 6 days of exposure can be used to prevent or modify measles in people without evidence of immunity.[13,63] IGIV at a dose of 400 mg/kg is recommended for people at high risk for severe, complicated measles, such as pregnant women without evidence of immunity and severely immunocompromised children, regardless of immunization or immunologic status.[13] IGIM at a dose of 0.5 mL/kg (maximum, 15 mL) should be given to all infants younger than 12 months of age who have been exposed to measles. Children with HIV/AIDS with severe immunosuppression or symptomatic disease or HIV-exposed infants with unknown infection status should receive IG prophylaxis after exposure to measles regardless of their measles immunization status.

To ensure immunogenicity, measles vaccine must be deferred after IG administration. The period of deferment depends on the dose and type of IG therapy.[13] Measles vaccination should be postponed for 3 to 6 months after the administration of IGIM for prophylaxis against tetanus, hepatitis A and B, rabies, measles, and varicella. When IGIV is used as replacement therapy or for the treatment of idiopathic thrombocytopenic purpura or Kawasaki disease, vaccination should be deferred for 8 to 11 months, and when blood or blood products are given, vaccination should be deferred for 3 to 7 months. No delay in vaccination is necessary after the administration of washed red blood cells. Children who receive monthly IGIV do not routinely require additional IG postexposure prophylaxis if the IGIV was given within 3 weeks.[13]

Public Health Measures and Outbreak Control

Healthcare personnel must immediately report suspected measles cases to their local health departments. Measles is a notifiable disease that requires reporting to the CDC within 24 hours. Control measures include initiation of outbreak investigation, patient follow-up, prioritization of contacts, voluntary isolation and quarantine, postexposure vaccination, and early MMR vaccine for infants between the ages of 6 and 11 months.[63,71,142]

Measles vaccine may provide protection against measles if given within 72 hours of exposure.[13,63] In institution-associated measles outbreaks (e.g., childcare centers, primary and secondary schools, colleges), all students and their siblings should be vaccinated unless they have documentation of immunity (i.e., receipt of ≥1 vaccine doses at or after age 12 months for preschool-aged children and 2 doses of measles vaccine for school-aged children, laboratory evidence of immunity, laboratory confirmation of disease, or born before 1957).[63] School personnel born in 1957 or later who have not had documented measles or 2-dose measles-containing vaccine also should be vaccinated.

For measles outbreaks in preschool-aged populations, vaccination efforts should focus on those who are not up to date with their measles vaccinations and on infants between 6 and 12 months of age who are not yet immunized.[13] Infants younger than 12 months who are vaccinated during an outbreak must be revaccinated at 12 to 15 months of age and again before school entry.

Healthcare personnel without documented immunization status or laboratory evidence of measles immunity must be vaccinated to prevent nosocomial transmission of measles. Exposed personnel should be relieved of direct patient contact for days 5 to 21 after exposure, regardless of their receipt of postexposure vaccine or IG.[13,13–145]

Isolation Procedures

Isolation of household or school contacts alone is not effective in preventing transmission because excretion of virus occurs before the onset of symptoms. Immunocompetent patients with measles should be isolated and placed on airborne transmission precautions until 5 days after the onset of rash. Immunocompromised people should be isolated for the duration of their illness.[146] Hospitalized patients exposed to measles should be isolated with airborne precautions for days 5 to 21 after exposure.[146]

Key Points

Epidemiology, Clinical Features, Diagnosis, and Prevention of Measles

Epidemiology

- Acute, vaccine-preventable viral disease of childhood; affects only humans

- Droplet and airborne transmission; highly contagious
- Natural infection results in lifelong immunity.
- Vaccination has resulted in dramatic declines in global incidence and mortality rates.
- Eliminated from the Americas; still endemic in many countries
- Importations into the United States continue to occur, resulting in cases and outbreaks, primarily involving unvaccinated people.
- Outbreak investigation carries a substantial economic burden.
- Eradication is biologically, programmatically, and operationally feasible.

Clinical Features

- All infections are symptomatic
- Incubation period of 8–12 days; patient contagious 4 days before until 4 days after rash onset
- Disease characterized most frequently by
  - Classic triad: cough, coryza, conjunctivitis with fever
  - Erythematous maculopapular rash that spreads in a cephalocaudal direction
  - Evanescent enanthem (i.e., Koplik spots) that appears on the lower buccal mucosa adjacent to the molars
- Complications include otitis media, pneumonia, and diarrhea; encephalitis occurs in 1 of 1000 cases; rare deaths from

pneumonia and neurologic complications.

- Rash can be absent in immunocompromised hosts.
- Case-fatality highest among infants

Diagnosis

- Serology (i.e., measles-specific immunoglobulin M) and virus RNA detection by reverse transcriptase polymerase chain reaction (RT-PCR) on clinical samples

Treatment

- Vitamin A treatment reduces risk of death for deficient children.
- No antiviral drugs are available.
- Antibiotic treatment for secondary bacterial complications (e.g., otitis media, pneumonia)

Prevention

- Measles vaccination remains a highly cost-effective public health intervention.
- Standard immunization at 12–15 months of age with a second dose at 4–6 years of age
- Measles-containing vaccines are safe and highly effective for immunocompetent children.
- High levels of population immunity through immunization are crucial for disease control and elimination.
- Human immune globulin is given to high-risk, exposed, susceptible contacts (e.g., infants <12 months of age, pregnant women, severely immunocompromised children).

RNA Viruses: Rhabdoviridae

OUTLINE

228 Rabies Virus

228

Rabies Virus

Rodney E. Willoughby Jr.

The Virus

Rabies virus and 14 similar viruses, including Australian, European, Lagos, Mokola, Duvenhage, Bokeloh, Ikoma, and Lleida bat lyssaviruses, are members of the Rhabdoviridae family, genus *Lyssavirus,* which is derived from the Greek word *lyssa,* meaning "madness." *Rabies* derives from the Sanskrit word *rabhas,* which means "to do violence."[1] Rabies virus and many lyssaviruses cause human encephalitis through zoonotic infection.[2]

The lyssaviruses differ antigenically but are morphologically similar and neurotropic.[3] Rabies virus is an enveloped, bullet-shaped virus that is 180 nm long and 75 nm wide and composed of five structural proteins (Fig. 228.1). Rabies virus contains one copy of a single-stranded, nonsegmented, negative (noncoding) RNA of approximately 12,000 nucleotides. The virus envelope contains glycosylated G-protein spikes that bind to cells. The matrix (M) protein is located on the inner virus envelope, inside which the virus nucleoprotein (N) tightly binds the viral RNA to form the nucleocapsid core. This core, along with a large transcriptase protein (L) and a phosphorylated protein (P), is the rabies virus nucleocapsid (RNP).

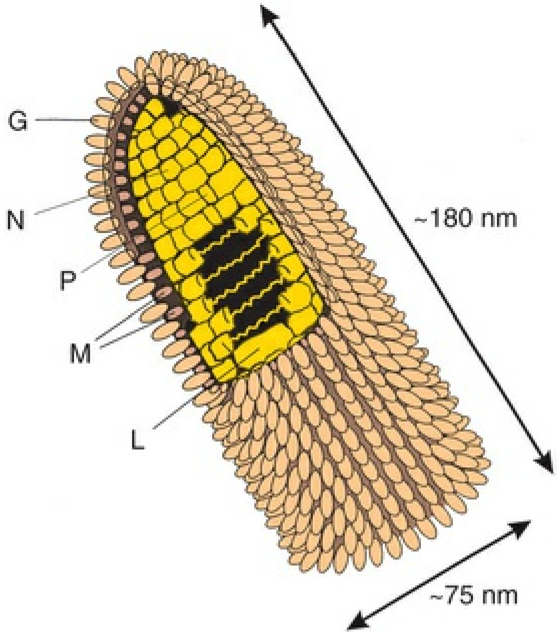

FIGURE 228.1 Hypothetical model of the rabies virion. The surface is covered by G glycoproteins (G) embedded in lipid membrane derived from the host cell. Matrix proteins (M) associate with the lipid membrane. Within this envelope is a ribonucleoprotein core composed of RNA closely associated with protective nucleoprotein (N), virion transcriptase (L), and phosphoprotein (P).

Pathogenesis

The incubation period after rabies virus inoculation begins with ill-defined local replication in muscle or skin for canine or bat rabies variants, respectively. This step in pathogenesis is the basis of the rationale for recommendations of local wound care and instillation of neutralizing antibody to reduce the rabies infectious inoculum. Neutralizing antibodies actually can penetrate the infected cells.[4] Response to the rabies vaccine then generates further neutralizing antibody.

After local tissue replication over weeks to months, the virus attaches to nicotinic acetylcholine receptors that provide access to the peripheral nervous system through neuromuscular spindles or muscle motor end plates. Sensory and autonomic nerves also are infected.[2] Other host receptors for rabies virus include specific carbohydrates, the neuronal cell adhesion molecule (NCAM), and the p75 neurotrophin receptor (p75NTR).[5]

Rabies virus moves centripetally along peripheral nerves, without virus replication, at rates of 100 mm/day or higher. After it is in the spinal cord, virus spreads rapidly to the brain, tracing neurons in retrograde fashion across synapses at a rate of one synapse per day. Centrifugal spread then occurs along motor, sensory, and autonomic axons into host body tissues (usually restricted to nerves innervating organs, including hair follicles) and particularly into the salivary and lacrimal glands.[6,7] Pathologic features are minimal. *Negri bodies* are rabies specific eosinophilic inclusions of RNPs and chaperonins in the cytoplasm of neurons that vary by brain region and may not be found in 30% of cases.[8] Histology shows perivenular lymphocytosis. Inflammation of the dorsal root ganglia correlates with focal neurologic prodromes.[9] In the less common paralytic form of rabies, axonal loss mimics acute motor axonal neuropathy and other polio-like diseases.[10] Minimal histologic damage is in stark contrast to the severity of clinical rabies. Rabies viremia and viruria are not mechanisms of virus spread.

Virulence and Immunity

Host factors that reduce the incubation period are (1) young age; (2) immunocompromised state, including corticosteroid use; (3) greater severity of the wound; (4) closeness of the wound to the central nervous system; and (5) large inoculum. Neuroinvasiveness is determined by the virus G protein. In animal models, a single-point mutation at position 333 of the G protein renders strains avirulent as a result of alteration in the ability of the virus to spread from cell to cell.[11] Overexpression of the G glycoprotein induces neuronal apoptosis and generates effective immunity.[12–14]

The G protein and the RNP are the major targets of the protective host response. The G glycoprotein is the major target of virus-neutralizing antibody and of cellular immunity.[15] Antigenicity of the G protein of rabies virus is broad enough to induce protective immunity to all rabies virus strains, but it may not protect against other lyssaviruses.[1]

Epidemiology

Rabies primarily is an animal infection. Humans become infected through exposure to infected animals. Worldwide data on the human burden of rabies are incomplete because of the hopelessness, stigma, and extreme poverty associated with populations at greatest risk for rabies. It is estimated that 50,000 to 60,000 people die annually of rabies. Most cases of rabies occur in males and children.[16]

The control of rabies requires knowledge of the endemic animal source of rabies and the geography of infection and an understanding of virus transmission in nature.[16,17] Any warm-blooded animal can become infected, but some animal species are more susceptible, and some rabies strains are more infectious than others.[18,19] Shedding of virus in saliva and the rapidity of death vary among animal species. Skunks shed virus for up to 18 days before death, whereas foxes succumb rapidly.

The dog remains the principal vector for transmission of rabies virus to humans in most parts of the world outside of North America and Europe. Cats usually are second in importance in these areas. In the Americas, with the waning of dog rabies and a broadening of the habitat of vampire bats, most rabies is transmitted by bats.[20] The source of rabies has shifted from domestic animals to wildlife (Fig. 228.2) in North America, where six separate rabies enzootics exist. Outside of North America, wildlife rabies enzootics involve other animals (Table 228.1). Other bat lyssaviruses have been isolated in Europe, Africa, and Australia and can cause sporadic human encephalitis with fatal outcomes.[21] Genetic sequencing and typing by monoclonal antibody panels can distinguish rabies enzootics and whether humans are infected with local or imported rabies virus strains.[22]

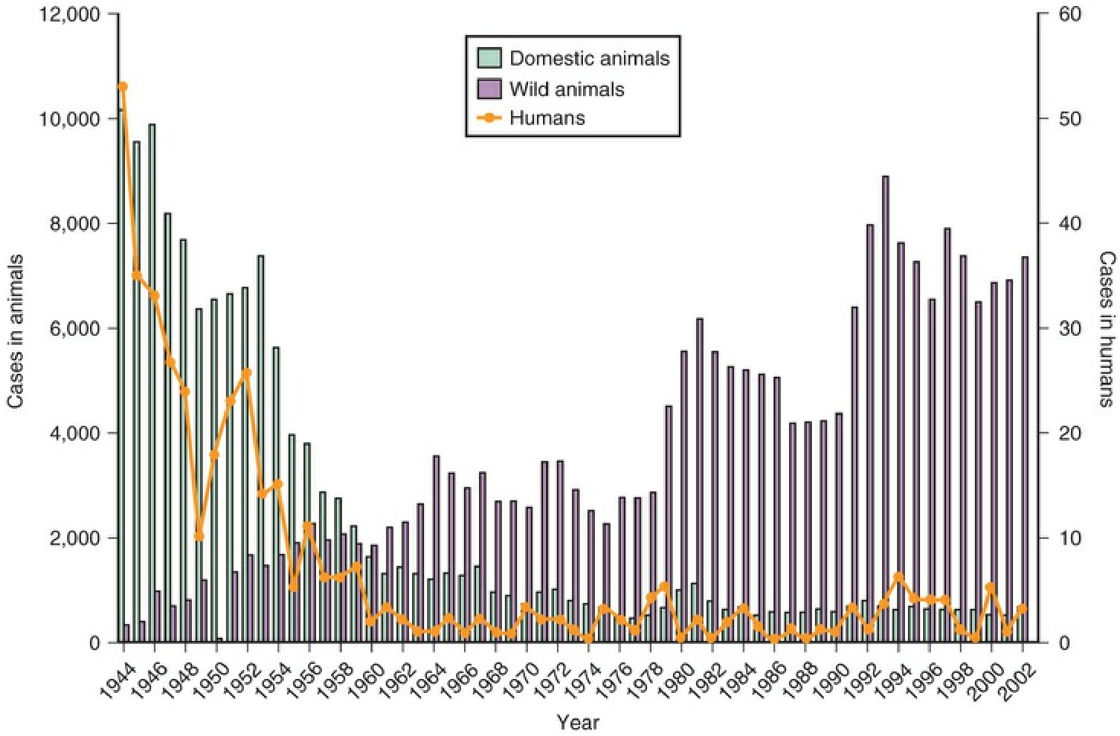

FIGURE 228.2 Temporal trends in animal and human rabies in the United States. (Modified from Rupprecht CE, Gibbons RV. Clinical practice: prophylaxis against rabies. N Engl J Med 2004;351:2626–2635.)

TABLE 228.1

Endemic Rabies in Wildlife

Geographic Region	Principal Species With Endemic Rabies[a]
United States and Canada	
Central United States and Canada	Striped skunk
Mid-Atlantic, southeast United States	Raccoon
New York, Quebec, Ontario	Red fox
Northwest territories	Arctic fox
Arizona	Grey fox
Texas	Grey fox
Caribbean	Mongoose
Europe	Red fox
Iran	Wolf
Africa	Jackal

[a] The bat is always considered endemically rabid. The dog is the principal vector for transmission of rabies around the world, except for North America and Europe.

The vehicle of virus transmission is infected animal saliva, which can be inoculated by a bite or scratch. Contact of infected animal saliva with human mucous membranes also can transmit infection.[23] Nine of 13 human cases of rabies reported in the United

States between 1980 and 1990 resulted from exposure to animals outside of the country.[22] In contrast, a history of animal exposure was absent in 78% of nontravelers and determined by molecular techniques to have been acquired from bats.[24] It is assumed that certain insectivorous bats inflict unperceived bites on sleeping persons.[23] In addition to animal transmission of rabies virus, there have been 4 outbreaks of solid-organ transplantation-associated rabies and 10 corneal implants transmitting rabies.[25,26]

Clinical Manifestations

Natural survivors of rabies are being increasingly reported, albeit with poor outcomes.[27,28] There also are reports of persons meeting laboratory definitions of rabies with milder disease[29–31] Serologic surveys document asymptomatic exposure in high-risk populations[32] The concept that rabies virus infection can cause a continuum of illness severity is being investigated.[33]

Clinical stages of human rabies correspond to steps in pathophysiology. The asymptomatic first phase is the virus incubation period, which usually lasts from 10 to 90 days but ranges from 4 days to 8 years.[34] The long incubation period lowers the yield of obtaining a history of an antecedent animal exposure. Retaking the history, focused on travel, immigration, occupations, and animal exposures, is critical.

The second, or prodromal, period lasts for 2 to 10 days and follows virus invasion into the central nervous system. Early symptoms, which occur in up to one half of patients, are nonspecific and include fever, dysphagia, and changes in behavior, sleep, and emotions. Local pruritus, pain, paresthesia, weakness, or myoclonic jerks occur at the site of inoculation in approximately 50% of cases and are most helpful in focusing the diagnosis on rabies. This stage correlates with virus infection of the dorsal root ganglia, spinal cord, brainstem, and limbic system.

The third stage is the development of central nervous system signs of disease. The *furious form* of rabies comprises aggressiveness (e.g., biting, hitting, yelling), excitement, hyperactivity, and hallucinations that last for brief periods and alternate with normal behavior, progressing to confusion or delirium. Fever can be intermittent but is invariably present. More than 50% of patients experience hydrophobia (with attempts to drink liquids) or aerophobia (when air is blown on the face). These reactions result from violent diaphragmatic contractions as an exaggerated respiratory protective reflex, and they are sufficient to cause pneumothorax. Hypersalivation and dysphagia increase the risk of aspiration. Status epilepticus, marked dystonia, parkinsonian signs, or opisthotonus are uncommon and should suggest other diagnoses. Clinical presentation at this stage can mimic that of intoxication, envenomation, meningitis, encephalitis, cerebral malaria, myoclonic epilepsy, tetanus, polio, or Guillain-Barré syndrome.

The *paralytic form* of rabies occurs in approximately 20% of patients and is slower to evolve. Flaccid paralysis progresses to quadriparesis, bulbar abnormalities, and respiratory insufficiency. Hypersalivation and hydrophobic spasms can occur. Guillain-Barré syndrome often is considered, but findings of fever, pain, sensory or sphincter disturbance, and more prominent involvement of proximal musculature are more suggestive of rabies.[9] In developing countries, where tissue-derived rabies vaccines are produced, vaccine-associated autoimmune encephalitis is a consideration. Other diagnostic possibilities include hysteria, botulism, and elapid snake bite.

Early deaths can result from respiratory arrest or cardiac dysrhythmias, including asystole. Recognized early, these events can respond to sedation.[35]

The fourth stage of rabies is coma, usually developing 6 to 8 days after hospitalization. Coma correlates with generalized spasm of the basilar arteries measured by transcranial Doppler ultrasonography and metabolic changes in cerebrospinal fluid (CSF) measured by nuclear magnetic resonance spectroscopy.[36,37] Examination results consistent with brainstem death are distinctively discordant with electroencephalographic (EEG) or magnetic resonance imaging (MRI) findings.[38–40]

The immune response to rabies usually is detected within 14 days after hospitalization. Complications associated with the immune response include complete heart block in dog rabies and cerebral edema in bat rabies. After 12 to 15 days, intracranial pressure and EEG activity drop acutely, and diabetes insipidus follows. Death usually occurs within 7 days of symptom onset in furious rabies and 21 days in paralytic rabies; critical care can prolong survival to a median of 18 days after hospitalization.

Laboratory Diagnosis

Rabies often is misdiagnosed clinically. CSF findings are typical of mild viral meningoencephalitis. CSF is normal in approximately one third of cases during the first week of illness. Electroencephalography, computed tomography, and MRI of the brain also can be normal.[41]

Specific laboratory tests that are not widely available are required for diagnosis. Aside from studies performed on brain tissue, virus-specific studies require tissue from sites reflecting the centrifugal movement of the virus. Detection of rabies virus antigen by immunofluorescence testing or culture of specimens obtained by skin-punch biopsies of the hair follicles at the nape of the neck has 50% to 94% sensitivity and almost 100% specificity. Reverse transcriptase polymerase chain reaction (RT-PCR) testing for rabies nucleic acid performed on the patient's saliva or skin has similarly high sensitivity and specificity.[42–44] Virus occasionally can be isolated from CSF, or its genome can be amplified from CSF or urine samples. Fluorescent immunohistology is a more sensitive method than histologic examination of brain tissue for Negri bodies and virus culture of brain tissue. Consideration should be given for brain biopsy at the time of placement of intracranial pressure-monitoring devices in patients with idiopathic encephalitis.

Rabies-specific antibodies in serum or CSF can be measured by indirect fluorescence assay (IFA) or enzyme immunoassay, and neutralizing antibody can be measured by the rapid fluorescent focus inhibition test (RFFIT) or fluorescent antibody virus neutralization (FAVN). Antibodies can be detected in serum as early as 6 days (and in CSF within 13 days) after the onset of symptoms.[24] Only clinical rabies, not rabies immunization, produces detectable rabies antibodies in the CSF.[24]

Treatment

Patients are intermittently alert until coma supervenes. Care should emphasize minimization of environmental stimuli that precipitate spasms, meticulous respiratory care, and control of pain and anxiety. Since the 1970s, intensive medical care has produced a few survivors. Two case series report an upper limit of 5% survival.[45,46] Recent case reports suggest a continuum of disease, which argues for greater survival benefit with intensive care.[29–32,47]

Limited animal experiments and human case reports suggest that inflammation is accentuated, paralytic disease precipitated, or death accelerated when persons with rabies receive rabies vaccine or rabies-specific immune globulin.[48–50] Use of broad-spectrum antiviral agents (e.g., vidarabine, ribavirin, interferon α) is unsuccessful and associated with massive brain necrosis.[51,52] A teenage girl survived rabies without prior receipt of postexposure prophylaxis (PEP). Her therapy included deep sedation to minimize dysautonomia. Administration of rabies vaccine and immune globulin were avoided.[53] Seven more survivors have been registered. An updated protocol and case registry of similarly treated patients are available at www.mcw.edu/rabies.

Prevention

Available Vaccines

Schedules and indications for administration of rabies vaccine and human-derived rabies immune globulin (HRIG) are shown in Tables 228.2 and 228.3. Three rabies vaccines are licensed in the United States: human diploid cell vaccine (HDCV), primary chick embryo cell vaccine (PCECV), and rhesus lung cell vaccine, absorbed (RVA), although RVA is no longer being produced. Outside of the United States, additional vaccines include purified Vero cell vaccine (PVRV) and purified duck embryo vaccine (PDEV). All of these vaccines can be used interchangeably, although it is preferable to use the same vaccine for the entire course of immunizations. In the United States, intramuscular administration is recommended.[54] In other countries, many of the cell culture vaccines are administered intradermally to reduce the dose volume to expense ratio.[55] Nerve tissue vaccines and suckling mouse brain vaccines are in declining use and should never be used if there is access to cell-culture–derived vaccines.[56]

TABLE 228.2

Rabies Immunization Schedules, United States[a]

Immunization Schedules	Dose	Route of Administration	Days
PRE-EXPOSURE PROPHYLAXIS			
Vaccine	1 mL	IM	0, 7, and 21–28
POSTEXPOSURE PROPHYLAXIS			
Vaccine	1 mL	IM	No previous immunization: 0, 3, 7, 14 Previously immunized: 0, 3
Human rabies immune globulin (HRIG)	20 IU/kg	Infiltrated at site of exposure	Immediately (if not immunized previously)

[a] International rabies immunization schedules conforming to World Health Organization recommendations are available at World Health Organization. WHO Guide for Rabies Pre and Post Exposure Prophylaxis in Humans. Updated 2013. http://www.who.int/rabies/PEP_Prophylaxis_guideline_15_11_2013.pdf.

TABLE 228.3

Schedule of Postexposure Prophylaxis for Rabies in the United States, 2015

Vaccination Status, Treatment	Regimen[a]
NOT PREVIOUSLY VACCINATED	
Wound cleansing	All postexposure treatment should begin with immediate, thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as a povidone-iodine solution should be used to irrigate the wounds
Human RIG	Administer at a dose of 20 IU/kg of body weight. If anatomically feasible, a *full dose* should be infiltrated around the wounds; any remaining volume should be administered IM at an anatomic site distant from vaccine administration. RIG should not be administered in the same syringe as the vaccine. Because human RIG can partially suppress the active production of antibody, no more than the recommended dose should be given
Vaccine (HDCV or PCECV)	One 1-mL dose IM (deltoid area) on days 0, 3, 7, 14[b]
PREVIOUSLY VACCINATED[c]	
Wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as a povidone-iodine solution should be used to irrigate the wounds
Human RIG	Should *not* be administered
Vaccine (HDCV or PCECV)	One 1-mL dose IM (deltoid area[d]) on days 0, 3[b]

[a] These regimens are applicable for all age groups, including children.

[b] Day 0 is the day on which the first dose of vaccine is administered.

[c] Any person with a history of pre-exposure vaccination with HDCV, RVA, or PCECV;

prior postexposure prophylaxis with HDCV, RVA, or PCECV; or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination.

[d] Deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh can be used. Vaccine should never be administered in the gluteal area.

HDCV, human diploid cell culture vaccine; IM, intramuscularly; PCECV, purified chick embryo cell culture vaccine; RIG, rabies immune globulin.

From Rupprecht CE, Briggs D, Brown CM, et al. Use of a reduced (4-dose) vaccine schedule for postexposure prophylaxis to prevent human rabies recommendations of the Advisory Committee on Immunization Practices. MMWR Recomm Rep 2009;59(RR-2):1–9.

Pre-exposure Prophylaxis

Pre-exposure prophylaxis with vaccine should be offered to people in veterinary medicine, wildlife management, and rabies laboratory work; spelunkers; and selected people who travel to areas where canine rabies is endemic. There is increasing interest in rabies vaccine as part of routine childhood immunizations in rabies endemic countries.[57]

It is not necessary to measure the antibody response, except in immunosuppressed patients or if risk is ongoing.[54] Aside from local and systemic reactions, which are usually mild, side effects include immune complex–mediated reactions (e.g., hives, angioedema, arthritis), most often after booster doses. Cell culture–derived, vaccine-associated neurologic diseases are unproven.[58] Pregnancy is not a contraindication to rabies vaccine.[58] Chloroquine interferes with antibody production after HDCV administration.[23]

Postexposure Prophylaxis

Postexposure management of a patient wounded by an animal begins with aggressive care of animal-induced wounds, including tetanus prophylaxis. Complete and thorough washing and repeated flushing (especially of larger wounds) is accomplished with soap, detergent, or disinfectant and water or water alone/ Suturing and occlusive dressings are avoided. Definitive wound repair is best accomplished as a second, elective procedure after the risk of bacterial superinfection is past. Failure of PEP often is ascribed to wound closure or lack of administration of rabies immune globulin.

After disinfection, judgment regarding whether a rabies exposure has been likely must be made. Close communication with the local public health department is warranted to obtain information about the prevalence of infected animal species and to ensure proper examination of animals. Two thirds of PEP courses can be avoided by submission of the suspect animal for examination of the brain[58] Prophylaxis usually is not required for contact with a vaccinated animal or when contact with a rabid animal has not violated the individual's skin barrier or involved a mucous membrane. Because few cases of human rabies have occurred from small rodent bites, vaccination is not recommended after these exposures.[23] In developed countries, bites from dogs and cats that remain healthy after 10 days of observation do not warrant prophylaxis. However, in developing countries where the risk of animal rabies is higher, vaccination should be given immediately and should be discontinued only if the observed animal remains healthy.

Immediate administration of rabies immune globulin and commencement of immunization are required for persons who are bitten by wild carnivores and bats and by dogs or cats known or suspected to be rabid. Because bats have infected people in the absence of a recognized bite, rabies prophylaxis is recommended for persons who were asleep or unattended in a room with a bat and others for whom it is impossible to exclude direct contact with a bat.

Passive immunization should be administered as early as possible to exposed people not previously immunized. Human rabies immune globulin (HRIG) should be given at a dose of 20 IU/kg, with the entire dose infiltrated into the wound if feasible. The volume can be diluted if insufficient to infiltrate the entire wound. Unused immune globulin can be injected intramuscularly into the gluteal or anterolateral thigh muscle with a different syringe and injection site from those used for the vaccine. HRIG is safe and free from serious side effects. It should be given at the time of the first vaccine dose, but HRIG is not beneficial if given later than 7 days after the first vaccination. Equine rabies immune globulin in a dose of 40 IU/kg often is used outside of North America. Because the product is purified, it is well tolerated and equally as effective as HRIG.

Postexposure immunization for previously unimmunized people requires 4 doses given into the deltoid muscle (never in the gluteal region) over 14 days.[54] It is not necessary to measure the antibody response, except in immunosuppressed patients. Children produce an immune response equivalent to that of adults. The immunization series can be stopped if the brain of the suspected rabid animal tests negative for rabies virus on direct fluorescent antibody testing or if the domestic dog or cat remains healthy during 10 days of observation[58] Regimens for immunization are summarized in Table 228.3.

Theoretically, human-to-human transmission can occur, but transmission to healthcare personnel has not been documented.[59,60] The patient should be placed in an isolation room, and gowns, gloves, masks, and goggles should be worn by anyone who has direct contact with the patient. Healthcare personnel who experience mucous membrane or parenteral exposure to potentially infected tissues or saliva should be considered for PEP. When rabies is not considered antemortem, an average of 80 to 150 healthcare personnel receive prophylaxis.[61] There are no data to support chemoprophylaxis with oral ribavirin or amantadine.

Ultimately, improved rabies prevention depends on immunization of domestic animals and wildlife vectors of rabies. Wildlife exposures are increasing (see Fig. 228.2).[58] Rabies is increasing internationally where deforestation displaces bat colonies, affluence increases pet ownership, or there is an increase in feral dog packs. Wildlife can be efficiently immunized against rabies by the oral route through the use of baits containing live, attenuated strains or recombinant poxviruses that produce G glycoprotein.[62] There is a need for less expensive rabies vaccine and immune globulin, especially in countries with a high incidence of human rabies.[56] It reflects poorly on all nations when rabies has been vaccine preventable for more than 130 years but is economically inaccessible to more than 50,000 children and adults annually worldwide.

Key Points

Characteristics of Rabies Virus and Infection

Virology

- Single negative-stranded RNA viruses of the family Lyssaviridae

- Marked tropism for the nervous system

Epidemiology

- Emerging, major zoonosis causing encephalitis, with 55,000 deaths annually in Africa and Asia
- Dogs are the major vectors worldwide, with bats predominant in the Americas. Wild animal reservoirs vary geographically.
- Predilection for children and males
- Prolonged and variable incubation period

Clinical

- Major furious form is characterized by febrile encephalitis with focal myoclonus and paresthesias with characteristic hydrophobia and aerophobia (when present); intermittent consciousness until late in the disease.
- Minor paralytic form is often confused with Guillain-Barré syndrome, but rabies shows sphincter disturbances and more sensory phenomena.
- Prominent vascular and metabolic dysfunction contribute to rabies encephalitis.
- Milder forms of rabies disease can occur.

Diagnosis

- Requires sending skin biopsy, saliva, serum, and CSF specimens to a World Health Organization rabies reference laboratory

Treatment

- Conventional therapy is palliative.
- Milwaukee protocol (www.mcw.edu/rabies) consists of sedation to minimize dysautonomia, metabolic support, and critical care.

- Immunization and human rabies immune globulin (HRIG) are avoided after the patient becomes symptomatic.

Prevention

- Pre-exposure prophylaxis (3 doses over 21–28 days) is indicated for travel to rabies-endemic areas and for high-risk occupations. Boosters (2 doses) are then required after an exposure.

- Postexposure prophylaxis consists of aggressive washing of wound and 4 doses of vaccine over 14 days plus HRIG. Immunocompromised patients receive 5 doses and require serologic confirmation.

RNA Viruses: Orthomyxoviridae

OUTLINE

229 Influenza Viruses

229

Influenza Viruses

Fatimah S. Dawood, Joseph Bresee

Influenza viruses cause annual winter epidemics of respiratory illness in temperate climates and have resulted in four influenza pandemics since 1900. The global burden of influenza and global variation in influenza virus circulation patterns are increasingly recognized.[1–3] In the United States, influenza is estimated to result in 3000 to 49,000 deaths and 55,000 to 431,000 hospitalizations annually.[4–6]

Among children, influenza virus infections are common, and influenza-associated hospitalization rates are highest for those younger than 2 years of age and those with underlying medical conditions.[7–14] Although more than 90% of seasonal influenza-associated deaths occur among persons 65 years of age or older, 40 to more than 200 influenza-associated deaths are estimated to have occurred annually among US children from 1977 through 2007.[4,15] During the 2009 A(H1N1)pdm09 pandemic, children were disproportionately affected and experienced the highest pandemic influenza attack rates and hospitalization rates.[16]

Influenza vaccination is the best method of influenza prevention. Influenza vaccines are currently approved for use in children at least 6 months of age.[17]

Microbiology

Three antigenic types of influenza virus (i.e., A, B, and C) are recognized. Influenza A viruses are further subdivided into multiple subtypes, and influenza B viruses are often divided into two lineages: influenza B/Yamagata and influenza B/Victoria.

Influenza A and B viruses contain eight segments of negative-sense, single-stranded RNA that code for 10 and 11 proteins, respectively.[18] Similar to other RNA viruses, influenza viruses replicate using RNA polymerases in a process that is error prone, leading to frequent mutations that give rise to genetically diverse virus populations or quasispecies.[19] In some instances, these quasispecies possess adaptive mutations and may persist and circulate. Adaptive mutations confer antigenic differences or resistance to influenza antiviral medications or allow transmission from one host species to another.[20]

Influenza viruses are irregular spherical (80 to 120 nm in diameter) or filamentous structures with surfaces that are studded with rod-shaped hemagglutinin (HA) and neuraminidase (NA) spikes (Fig. 229.1).[21] These surface glycoproteins are the major targets of the protective host immune response, and they form the basis for influenza A virus subtyping.[22–24] Influenza C virus lacks NA.[25]

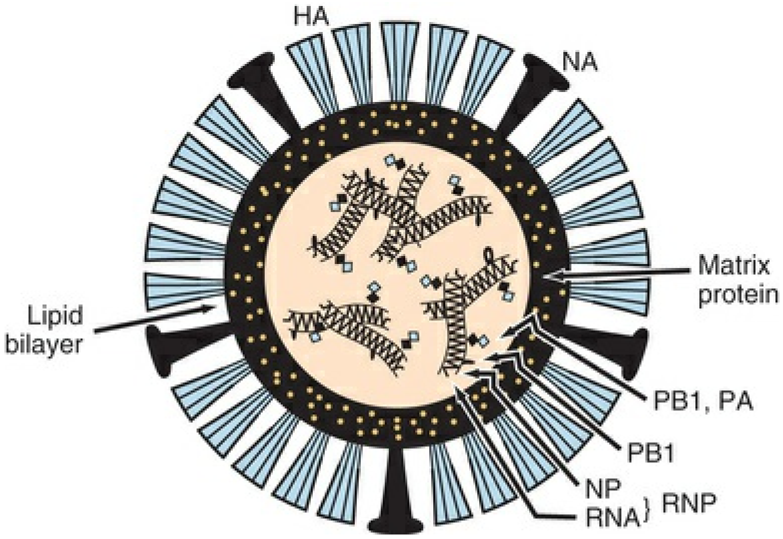

FIGURE 229.1 The influenza virus virion. HA, hemagglutinin; M, matrix protein; NA, neuraminidase; NP, nucleoprotein; PA, polymerase acidic protein; PB1, polymerase basic 1 protein; RNP, ribonucleoprotein. (Modified from Betts RF. Influenza virus. In: Mandell GL, Bennett JE, Dolin R [eds]. Principles and Practice of Infectious Disease, 4th ed. New York, Churchill Livingstone, 1995, p. 1546.)

HA is the attachment protein. It is synthesized as a single polypeptide chain that undergoes proteolytic cleavage to yield HA1 and HA2.[18,26] Cleavage of HA is required for infectivity, and increased cleavability is associated with excess virulence.[27,28] HA is expressed on the surface as a trimer, and it binds to sialic acid, which is the receptor for influenza viruses. Avian and human influenza A viruses preferentially bind to sialic acids with different oligosaccharide side chains.[29,30] NA is synthesized as a single polypeptide chain and is expressed on the surface as a tetramer.[31] This protein destroys sialic acid, the receptor recognized by HA, facilitating the release of progeny virions from the infected cell.

Aquatic birds are the natural hosts of influenza A viruses, and viruses bearing most subtypes of HA and NA have been isolated from birds.[32] Two influenza A subtypes that had not been previously isolated from birds and with evolutionarily distinct genomes were isolated from bat populations in Central America, suggesting that bats may be another reservoir for influenza A viruses.[33,34] Influenza A viruses also have been isolated from pigs, cattle, horses, dogs, cats, seals, whales, penguins, and nonhuman primates. Infections with influenza B viruses have been identified in seals.[35,36] Influenza C viruses infect only humans.

The standard convention for nomenclature of influenza viruses takes into account the variability in influenza surface proteins. Virus designations specify type, host (for strains of animal origin), geographic source, strain number, and year of isolation, followed by the HA and NA subtypes in the case of influenza A viruses (Box 229.1)[37]

Box 229.1

Standard Nomenclature for Influenza Viruses

Type/host species (if not human)/location where isolated/strain number/year of isolation and hemagglutinin and neuraminidase subtype for influenza A viruses

Antigenic Drift and Antigenic Shift

Genetic mutations that result in changes in viral HA and, to a lesser extent, in NA are responsible for the ability of influenza viruses to cause annual worldwide epidemics. Minor changes in the antigenic characteristics of the HA and NA of influenza A and B viruses, called *antigenic drift,* result from an accumulation of point mutations in the genes encoding these proteins. Antigenic variants responsible for annual epidemics arise continually when point mutations allow viruses to escape neutralization by antibodies directed against previously circulating strains.[38]

Antigenic shift is a major antigenic change that occurs when an influenza A virus that bears a novel HA (or novel HA and NA) emerges in the human population. Antigenic shift is a rare event that is responsible for worldwide epidemics (i.e., pandemics) and occurs solely in influenza A viruses. Antigenic shift occurs when a nonhuman influenza virus directly infects human hosts or when a new virus is generated by genetic reassortment between nonhuman and human influenza viruses.[38] The segmented genome of influenza viruses facilitates reassortment events.

Swine are thought of as mixing vessels for the emergence of novel recombinant viruses derived from human and avian viruses because swine possess the sialic acid α2,3-galactose–linked receptors to which avian influenza viruses preferentially bind and the sialic acid α2,6-galactose–linked receptors to which human influenza viruses bind preferentially.[39] However, reassortant viruses can be generated in any host that is coinfected with two influenza A viruses.

Influenza Pandemics of the 20th and 21st Centuries

Since 1900, four pandemics have occurred with the emergence of novel influenza A viruses: the 1918 H1N1 Spanish flu pandemic, the 1957 H2N2 Asian flu pandemic, the 1968 H3N2 Hong Kong flu pandemic, and the 2009 H1N1 pandemic. During the 1918, 1957, and 1968 pandemics, the strains that emerged were novel influenza A subtypes that replaced the previously circulating subtype and became established as the predominant circulating influenza A subtype.

In 1977, H1N1 viruses reappeared after a 20-year absence (since the 1957 H2N2 pandemic) and caused disease in children and young adults who lacked previous exposure to H1N1 viruses. H1N1 viruses subsequently began circulating in the human population but did not replace the H3N2 viruses. Instead, influenza A H1N1 and H3N2 viruses continue to cocirculate.

In April 2009, cases of human infection with a novel influenza A (H1N1) virus were identified. This novel virus possessed a unique combination of gene segments, including genes that originated from swine, avian, and human influenza viruses that were established in pigs in North America and Europe (Fig. 229.2). By June 2009, this virus, now referred to as A(H1N1)pdm09, was causing widespread illness throughout the world, and it continues to circulate worldwide as a seasonal influenza virus.[40,41]

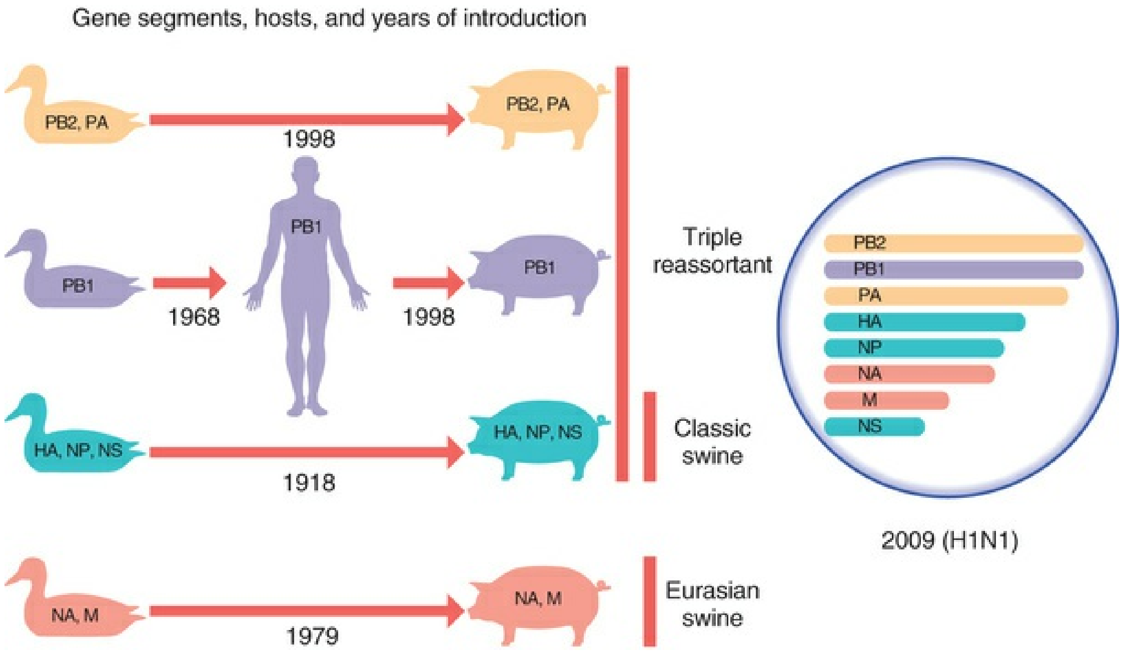

FIGURE 229.2 Host and lineage origins for the gene segments of the 2009 influenza A (H1N1) virus. HA, hemagglutinin; M, matrix; NA, neuraminidase; NP, nucleoprotein; NS, nonstructural; PA, polymerase acidic; PB1, polymerase basic 1; PB2, polymerase

basic 2. (Modified from Garten RJ, Davis CT, Russell CA, et al. Antigenic and genetic characteristics of swine-origin 2009 A(H1N1) influenza viruses circulating in humans. Science 2009;325:197–201.)

Sequence analysis of the 1918 pandemic influenza A (H1N1) viruses suggests they resulted from adaptation of avian H1N1 influenza A viruses to the human population.[42] The HA of avian influenza viruses exhibits receptor-binding specificity for sialic acid residues with α2,3 linkages expressed in the gastrointestinal tract of waterfowl and the lower respiratory tract of humans, whereas the HA of human influenza viruses exhibits receptor-binding specificity for sialic acid residues with α2,6 linkages expressed in the upper respiratory tract of humans. Some 1918 pandemic viruses possess dual binding specificity for sialic acid α2,3- and α2,6-galactose–linked receptors, but it is unclear whether this dual specificity accounts for the increased virulence attributed to the viruses.[43,44]

Pathogenesis

Influenza virus transmission is thought to occur primarily through large-particle respiratory droplets. Transmission by contact with contaminated surfaces also occurs, and limited data suggest a possible role for aerosol transmission of influenza virus by small-particle droplet nuclei.[45–51]

Influenza viruses infect the columnar epithelial cells of the respiratory tract. Peak virus replication occurs 1 to 3 days after inoculation. Virus shedding continues for 6 to 8 days in adults and can persist for more than 13 days in young children or immunocompromised people.[52–54] Necrosis of epithelial cells, edema, and inflammation occur rapidly.[55] Most infections are confined largely to the upper airways, but infection can spread to involve smaller airways such as the bronchioles and alveoli. In the absence of bacterial superinfection, epithelial cell recovery begins within 3 to 5 days, but complete restoration of ciliary function and mucus production takes about 2 weeks.

In experimental human influenza A virus infection in healthy adults, interleukin-6 (IL-6) and interferon α (IFNα) concentrations in nasal lavage fluid peak on day 2 and correlate directly with viral titers, temperature, mucus production, and symptom scores.[56] Tumor necrosis factor-α (TNF-α) responses peak later as viral shedding and symptoms are subsiding, and IL-8 responses peak late in the course of illness (i.e., days 4 to 6) and correlate only with lower respiratory symptoms. A study that enrolled patients with community-acquired influenza found that plasma and nasal lavage levels of IL-6 correlated best with symptoms, whereas TNF-α correlated with fever but not with other symptoms and peaked only after fever and other symptoms had already declined.[57]

Immunity

During influenza infection, death of virus-infected cells is mediated by antibody-dependent cellular cytotoxicity, antibody plus complement, cytotoxic T lymphocytes (CTLs), or apoptosis.[58,59] The development of influenza-specific CTLs is important for clearance of virus and recovery from illness. Clearance of virus is delayed in people with T-lymphocyte immunodeficiency states.[60] CD8$^+$ class I histocompatibility antigen-restricted CTL subsets recognize CTL epitopes in surface glycoproteins and internal proteins and confer subtype-specific and cross-reactive species immunity.[61] Subsets of lymphocytes with a CD4$^+$ class II histocompatibility antigen phenotype augment B-lymphocyte–mediated antibody production and CD8$^+$ cell proliferation.[61] Intracellular targeting of processed antigen or interaction with the major histocompatibility complex may lead to differential recognition by class I– and class II–restricted CTLs.

Influenza virus infection induces the production of local and humoral antibodies to HA and NA. Antibodies to HA are critical for virus neutralization, and those to NA reduce virus replication.[18,23] Although antibodies to nucleocapsid and matrix proteins are detectable, they do not appear to provide protection.[23] Protection afforded by CTLs or cross-reactive antibodies is limited. Subtype-specific, antibody-mediated protective immunity to influenza is durable over many years, but antigenic variation in HA and NA may compromise this immunity.[62]

Epidemiology

In temperate climates, influenza epidemics occur annually, typically during the winter months, whereas in some tropical climates, influenza viruses circulate year round or circulate more during rainy seasons.[63,64] Influenza A and B viruses can circulate at the same or different times, and the severity of influenza epidemics varies substantially from year to year, depending on the predominant circulating strains. In temperate climates, epidemics of influenza and respiratory syncytial virus (RSV) or other respiratory viruses often occur at about the same time during the winter.[65,66]

Influenza A H3N2 viruses usually cause the more severe influenza epidemics (as measured by overall mortality or hospitalization rates), whereas influenza A H1N1 and influenza B viruses often result in relatively milder epidemics.[67] Mortality and hospitalization rates may not reflect the full impact of influenza in some seasons. For example, during the 2009 A(H1N1)pdm09 pandemic, which disproportionately affected children and younger adults, overall severe morbidity and mortality rates were lower than in some influenza A (H3N2) predominant seasons, when most severe infections occur among older persons with comorbidities.[68]

Impact of Seasonal Influenza on Children

Influenza virus infection and illness occur most commonly among school-age children.[69–71] Children play an important role in sustaining community epidemics of influenza A and B because of the high attack rate of influenza among young children and because they shed infectious virus for longer periods and at higher titers than adults. Adults in homes with young children have a significantly higher risk of influenza illness than adults without child contact.[69] In a community outbreak, peaks of influenza among children typically precede peaks of influenza among adults, and early in an epidemic, school absenteeism precedes work absenteeism.[72] In a prospective survey of 313 schoolchildren, influenza accounted for an excess of 28 illness episodes, 63 missed school days, 22 secondary illnesses in families, and 20 days of missed parental work per 100 children.[73]

Influenza results in a substantial number of outpatient and inpatient visits for children. An estimated 89 to 620 emergency department visits and 2 to 16 hospitalizations per 10,000 children younger than 5 years of age occur due to influenza annually in the US.[74] Among infants younger than 6 months of age, an estimated 9 to 104 hospitalizations occur per 10,000 children, and hospitalization rates exceed hospitalization rates for healthy adults 65 years of age or older during some seasons.[7,10,11,14,75–77] Influenza-associated hospitalization rates are higher among children with cardiac and pulmonary conditions than among healthy children.[78,79] Children with neurologic and neuromuscular conditions are at increased risk for severe illness, respiratory failure, and prolonged hospitalization associated with influenza.[78,80–82]

Deaths of children attributed to laboratory-confirmed influenza became a nationally reportable disease in the US in 2004. Of laboratory-confirmed, influenza-associated deaths reported during the 2004–2012 period, almost one half occurred among previously healthy children and one third occurred among children with neurologic disorders.[83]

2009 A(H1N1)pdm09 Pandemic

During the spring of 2009, a novel influenza A (H1N1) virus that resulted in a pandemic was identified.[40] An estimated 61 million illnesses, 274,000 hospitalizations, and 12,500 deaths associated with the A(H1N1)pdm09 virus occurred in the US during the first year.[84] The highest estimated attack rates in the US occurred among children and young adults, and the highest estimated hospitalization rates occurred for children younger than 5 years of age.[16] Globally, an estimated 284,500 deaths associated with the novel virus occurred during the first year of A(H1N1)pdm09 circulation.[2]

Clinical Manifestations

Clinical manifestations of influenza virus infection vary according to the age of the host (Table 229.1). Infants with influenza virus infection can manifest irritability, difficulty feeding, or fever alone and can have clinical presentations that are difficult to distinguish from that of bacterial sepsis.[85] In neonates, influenza virus infection can result in apnea.[86]

TABLE 229.1

Common Manifestations of Influenza Illness in Children

Age	Manifestation	Frequency
Infant, toddler <5 years old	Afebrile URI	+
	Febrile URI	+++
	Acute otitis media	++
	Pneumonia	+
	Laryngotracheobronchitis	+
	Bronchiolitis	+
	Sepsis syndrome	+
Child ≥5 years old	Afebrile URI	+
	Flu-like syndrome[a]	+++
	Acute otitis media	++
	Pneumonia	+
	Myositis	+
	Myocarditis	Rare
	Encephalopathy	Rare

[a] Fever, cough, headache, myalgia, and malaise.

URI, upper respiratory tract infection; +++, most common manifestation; ++, common manifestation; +, infrequent manifestation.

Among preschool and school-age children, fever and signs of respiratory tract involvement, including laryngotracheobronchitis, are common. Gastrointestinal symptoms, including nausea, vomiting, and diarrhea, also can occur and are more common in preschool-aged children than in older age groups.[87,88] Older children and adults are more likely to have an abrupt onset of fever and chills accompanied by headache, sore throat, myalgia, malaise, anorexia, and a dry cough.[38]

The younger the child, the greater the overlap between influenza and syndromes caused by other viruses, particularly infections caused by RSV, adenovirus, and parainfluenza virus.[89,90] In a study of hospitalized children younger than 6 years of age, fever and cough together had a sensitivity of 54% for detecting influenza virus infection but a positive predictive value of only 16%, which increased to 25% when the analysis was limited to periods when at least one influenza virus infection was detected per week among study participants.[66] In another study that included children 17 years of age and younger, the triad of cough, headache, and pharyngitis as a predictor of laboratory-confirmed influenza in children during influenza season had a sensitivity of 80% and specificity of 78%.[91]

Upper respiratory tract illness caused by influenza is characterized by a dry, hacking cough that peaks after 3 to 4 days and persists for more than 1 week after other symptoms resolve. Sore throat occurs frequently, but it is not associated with exudative pharyngitis. Patients may complain of rhinorrhea and eye discomfort (i.e., tearing, photophobia, or burning). Croup syndrome associated with influenza tends to be more severe than that associated with parainfluenza virus; secretions are tenacious, and fever is typically higher. Airway compromise is often more severe and is sometimes complicated by bacterial superinfection.[92]

Most episodes of bronchopneumonia are mild and associated with complete recovery. A history of high fever (often >39°C), epidemic influenza in the community, and recent flu-like symptoms in other family members may help differentiate influenza pneumonia from infections caused by other respiratory viruses. Rarely, pneumonia due to influenza can be fatal in previously healthy individuals.[93–95]

Complications

Complications involving the upper and lower respiratory tract of influenza include acute otitis media (AOM), sinusitis, bronchiolitis, croup, and pneumonia. AOM was diagnosed in 35% of children 6 months through 3 years of age who had influenza-associated upper respiratory tract infections (URIs) in one prospective study.[96] In other studies, influenza virus was isolated from middle ear fluid in 3% of all children with AOM and accounted for 5% to 28% of all cases of viral otitis media.[97,98] AOM associated with viral URI typically manifests 3 to 4 days after the onset of the URI.[99]

Influenza-associated pneumonia has been reported for 8% to 15% of children hospitalized with influenza.[80,100,101] Radiographically confirmed pneumonia associated with influenza can be primary viral pneumonia or secondary bacterial pneumonia. Secondary bacterial pneumonia is characterized by the appearance of fever and a productive cough during convalescence, along with radiologic evidence of lobar consolidation.[38] *Streptococcus pneumoniae* and *Staphylococcus aureus* are the most frequent bacterial causes of pneumonia and other bacterial coinfections in children with influenza, and an increasing proportion of coinfections with *S. aureus* are methicillin resistant.[102–106] In addition to severe, progressive pneumonia, *S. aureus* superinfection has been associated with bacterial tracheitis and toxic shock syndrome.[92,107] Infection with *S. aureus* is thought to enhance cleavage of viral HA, increasing the virulence of influenza viruses.[108] Bacterial coinfections in children with influenza are associated with more severe illness and poorer outcomes.[105,109–111]

Myocarditis and evidence of cardiac muscle damage associated with electrocardiographic changes, disturbances in cardiac rhythm, and elevated levels of cardiac enzymes are rare complications after influenza A and B infection.[38] Febrile convulsions are associated with influenza infection in infants and young children and have been reported in up to 20% of children 6 months to 5 years of age who were hospitalized with influenza.[104,112,113] Encephalitis and encephalopathy are unusual complications of influenza virus infection. Sporadic cases of influenza-associated encephalitis or encephalopathy have been reported from several countries, including the US, but most reported cases have occurred in Japan.[114,115] In two large case series of patients with influenza-associated encephalitis or encephalopathy in Japan, most reported cases were for children younger than 5 years of age. Patients had a range of neuropsychiatric symptoms, including seizures, altered consciousness, and psychotic behavior. Up to 28% of patients had persistent neurologic sequelae, and 27% to 32% of patients died.[116,117] Other neurologic complications associated with influenza include transverse myelitis, Guillain-Barré syndrome, and Reye syndrome.[38] Reye syndrome (i.e., encephalopathy and fatty degeneration of the liver) has become uncommon since recognition of the association between Reye syndrome and concomitant aspirin use and influenza in children.[118–120]

Myositis, characterized by acute pain and tenderness in the gastrocnemius and soleus muscles that is severe enough to limit walking, can occur within 1 to 3 days of influenza symptom onset. Myositis has been observed more often with influenza B than with influenza A virus infection.[121] Serum creatine kinase concentrations often are elevated transiently. Complete recovery usually occurs in 3 to 4 days. Associated rhabdomyolysis and renal failure occur rarely. Acute parotitis associated with influenza virus infection has also been observed during some epidemics.[122]

Influenza virus infection can cause exacerbations of underlying illness, particularly in children with preexisting pulmonary disease such as asthma and cystic fibrosis.[123] Patients with cystic fibrosis who have influenza virus infection have lower expiratory flow rates than those with other nonbacterial infections.[124,125]

Laboratory Findings

The peripheral white blood cell count usually is normal. Relative lymphopenia is typical in older children, and neutrophilia with a left shift occasionally is observed in infants. The radiographic appearance of lower respiratory tract influenza infection is not distinguishable from that of infection caused by other respiratory viruses.[126] Peribronchial infiltrates, hyperexpansion, and segmental or lobar atelectasis are common; interstitial infiltrates and pleural effusions are uncommon. Influenza pneumonia can evolve from peribronchial infiltrates to a more diffuse alveolar process in cases of fatal disease.[94]

Diagnosis

Because of overlap with the clinical presentation of other respiratory tract infections, influenza cannot be diagnosed definitively on the basis of clinical signs and symptoms or epidemiologic patterns.[65] In one study, the diagnosis of influenza in children based on clinical signs and symptoms during the influenza season was 38% sensitive and 91% specific compared with laboratory confirmation of influenza virus infection.[127] Establishing the diagnosis of influenza through laboratory testing, especially in hospitalized patients and those at high risk for severe influenza, can limit inappropriate antibiotic use, guide antiviral therapy, and provide data for influenza surveillance purposes.

Influenza diagnostic tests based on examination of nasopharyngeal aspirates, nasopharyngeal swabs, or nasal swabs include tissue or cell culture, reverse transcriptase polymerase chain reaction (RT-PCR), rapid antigen detection tests, and immunofluorescence assays (Table 229.2).[128] Sensitivity of these diagnostic tests is affected by the quality of the respiratory specimen and the timing of specimen collection. Nasopharyngeal or nasal specimens are preferred to throat swab specimens. Diagnostic yield is highest when specimens are collected within the first few days of illness, when influenza virus shedding is at its peak.[52]

TABLE 229.2

Influenza Diagnostic Testing Options

Diagnostic Test	Advantages	Disadvantages
Rapid antigen test	Provides results in 30–60 minutes	Variable sensitivity
	Some may differentiate influenza types but not subtypes	
	High specificity (63%–100%)	
DFA and IFA stain	Provides results in 2–4 hours and has high specificity (>80%)	Sensitivity depends on technical skill of operator
Real-time RT-PCR	Considered the gold standard diagnostic test; can provide results in 6–8 hours	
	High sensitivity and specificity	
Virus culture	Yields isolates that can be typed, subtyped, and characterized antigenically and genetically	May take ≥3days to obtain results
	High sensitivity and specificity	
Serology	Useful during outbreak investigations and epidemiologic studies; can detect past infection	Requires acute and convalescent sera; results usually not available to inform clinical decision making in acute setting

DFA, direct fluorescence assay; IFA, immunofluorescence assay; RT-PCR, reverse transcriptase polymerase chain reaction.

Real-time RT-PCR is considered the gold standard for detection of influenza viruses. It provides results within 6 to 8 hours, can be combined with detection of other respiratory viruses in a multiplex format, and allows typing, subtyping, and strain identification by sequence analysis of influenza viruses.[129,130] Virus culture is less sensitive than real-time RT-PCR for detection of influenza viruses, but it yields isolates that can be typed, subtyped, and characterized antigenically and genetically. With conventional culture, results are not available for 3 or more days. The shell vial culture technique provides results sooner than conventional techniques, with results available in 18 to 48 hours.[128]

Rapid antigen diagnostic tests have highly variable sensitivities but high specificities for detecting influenza in specimens from children. In a meta-analysis of studies comparing rapid tests to real-time RT-PCR or virus culture for children, the overall sensitivity was 67%, and specificity was 98%.[131] Rapid tests can provide results within 30 to 60 minutes, and some can differentiate between influenza A and B viruses. There are no licensed rapid tests that differentiate influenza A virus subtypes.

Because of the potentially low sensitivity of influenza rapid tests, results must be interpreted in the context of local influenza surveillance data. If the influenza rapid test is negative, but the patient has symptoms consistent with influenza, the patient may still have influenza, and clinicians should use clinical judgment when deciding whether to obtain additional influenza testing (e.g., real-time RT-PCR, culture) or initiate antiviral therapy. Interpretation of a positive rapid influenza test result also is problematic when the prevalence of influenza among people with respiratory illness is low.[132]

Direct and indirect fluorescent antibody tests have a specificity of more than 80%, but they have highly variable sensitivities compared with virus culture.[133] Serologic testing of acute and convalescent specimens for the presence of antibodies to influenza viruses can be useful for clinical studies and outbreak investigations, but they do not provide timely data.

Treatment

Two classes of antiviral drugs are licensed for the treatment of influenza in the US: the adamantanes, which are ion channel inhibitors and are active against influenza A viruses but not against influenza B viruses, and the NA inhibitors, which are effective against influenza A and influenza B viruses. The adamantanes have not been recommended for treatment of influenza during most recent influenza seasons because of widespread resistance among the circulating influenza viruses.[134,135] A third class of antiviral drugs, RNA-dependent RNA polymerase inhibitors, is licensed for the treatment of influenza only in Japan.[136]

Adamantanes

The adamantanes include the oral medications amantadine and rimantadine. These drugs block the M2 ion channel on influenza A viruses that maintains the acidity of the Golgi microenvironment and permits virus uncoating.[137] Amantadine and rimantadine are approved by the US Food and Drug Administration (FDA) for prophylaxis of influenza in children 1 year of age or older, but only amantadine is approved for treatment of influenza in children.

In studies of the use of adamantanes for the treatment of influenza in adult patients, amantadine or rimantadine therapy begun within 48 hours of the onset of symptoms was associated with a rapid reduction in fever, systemic complaints, and virus shedding.[138–140] Data on the effectiveness of adamantane treatment of children are limited. Treatment with rimantadine appears to reduce viral shedding rapidly in most patients, but shedding of resistant virus late in therapy has been observed.[141,142]

Amantadine is excreted renally, and dosage adjustments must be made for patients in renal failure.[143] Rimantadine also is excreted renally and requires substantial hepatic metabolism before clearance, necessitating dosage adjustments for patients with hepatic dysfunction or renal failure.[143]

Neuraminidase Inhibitors

The NA inhibitors licensed for the treatment of influenza in children in the US include zanamivir, which is available as an inhalational agent, and oseltamivir, which is available as a liquid suspension or tablet. Peramivir, a NA inhibitor available as an intravenous agent, is licensed for the treatment of uncomplicated influenza in adults 18 years of age or older. The NA inhibitors bind to the influenza neuraminidase enzyme active site, inhibiting the release of virions from the infected cells.[137]

Inhaled zanamivir is FDA approved for treatment in children 7 years of age or older and for chemoprophylaxis in children 5 years of age or older. Oseltamivir is approved for chemoprophylaxis of influenza in children 1 year of age or older and for treatment in children 2 weeks of age or older. Intravenous zanamivir is being studied for use in the treatment of influenza.[144]

Inhaled zanamivir and oral oseltamivir reduce the duration of illness due to influenza in children when treatment is initiated early in the course of illness. In one randomized, placebo-controlled trial involving children 4 to 12 years of age and three trials involving adults and children 12 years of age or older, zanamivir shortened the duration and severity of influenza symptoms when initiated within 48 hours of illness onset.[145–147] In randomized, controlled trials of oseltamivir efficacy among children in the outpatient setting, oseltamivir treatment within 24 to 48 hours of illness onset reduced the duration of illness and virus shedding, overall illness severity defined by composite symptom scores, and the incidence of AOM.[148–150] In a randomized trial enrolling children with asthma and influenza, oseltamivir reduced the incidence of asthma exacerbations and improved pulmonary function during the illness period. A Cochrane review of randomized trials evaluating oseltamivir concluded that oseltamivir reduced illness duration by a mean difference of 1 day compared with placebo among previously healthy children but found no effect among children with asthma.

Data on the effectiveness of oseltamivir treatment of hospitalized children is limited largely to observational studies, in part because evaluating efficacy against severe outcomes in hospitalized children would require enrollment of prohibitive numbers of children due to the relative infrequency of severe outcomes in the pediatric population.[151–154] Although some observational studies of hospitalized children have found an association between oseltamivir treatment or early treatment and reductions in length of hospital stay, risk of mechanical ventilation, and death, others have found no treatment effect.[151–155] A potential limitation of these observational studies is bias if patients treated early with oseltamivir are substantially different from those who are untreated or treated late.

Peramivir treatment of uncomplicated influenza in adults reduces the duration of illness. Two randomized trials that evaluated a single intravenous dose of peramivir compared with placebo in adults in the outpatient setting found that peramivir reduced illness duration by 1 day.[156] However, a trial of a 5-day course of intravenous peramivir compared with standard of care that included hospitalized adults and children 6 years of age or older found no effect from treatment on length of hospitalization.[157]

Zanamivir is concentrated in the respiratory tract; 10% to 20% of the active compound reaches the lungs, and the remainder is deposited in the oropharynx. Only 5% to 15% of the total dose is absorbed and excreted in the urine. Therefore, zanamivir dosage adjustment is not required for patients with renal failure. The estimated concentration of the drug in the respiratory tract is more than 1000 times the 50% inhibitory concentration (IC_{50}) for NA, and the inhibitory effect begins within 10 seconds.

Nebulized zanamivir should not be used in intubated patients because it may lead to ventilator failure and subsequent death.[158] Postlicensure reports indicate that inhaled zanamivir can cause cough, bronchospasm, and a reversible decrease in pulmonary function.[136] If patients with pulmonary dysfunction receive zanamivir, they should have a fast-acting bronchodilator available and discontinue zanamivir if respiratory difficulty develops.

Oseltamivir is readily absorbed from the gastrointestinal tract and is converted by hepatic esterases to the active compound that is widely distributed in the body. The half-life of oseltamivir is 6 to 10 hours. Oseltamivir is excreted primarily through the kidneys, and the dosage must be modified in patients with renal insufficiency. The most commonly reported side effects are nausea, vomiting, and diarrhea.

Peramivir is excreted renally and requires dose adjustment for patients with renal insufficiency. The half-life of peramivir is 12 to 25 hours.[136,159] The most commonly reported side effects of peramivir are diarrhea, nausea, and vomiting; decreased neutrophil count also has been associated with treatment.[136] Data on peramivir use in children is limited largely to studies from Japan, where peramivir has been licensed since 2010, and to the 2009 H1N1 pandemic, when peramivir was approved for treatment of critically ill hospitalized patients in the US under an FDA Emergency Use Authorization. Available data indicate that intravenous peramivir usually is well tolerated in children.[160–162]

Antiviral Treatment in Infants

Oseltamivir is the only influenza antiviral medication licensed for the treatment of influenza in infants at least 2 weeks of age, and specific dosing guidelines are available for this age group.[163,164] Separate dosing is necessary for preterm infants because immature renal function may result in slower and variable drug clearance.[163–165] Of 72 children younger than 1 year of age who received 3 to 3.5 mg/kg/dose of oseltamivir carboxylate twice daily for 5 days in a prospective phase I/II study, none experienced moderate or severe adverse events.[166] In a randomized, placebo-controlled trial of oseltamivir treatment in hospitalized children, oseltamivir was well tolerated with no difference in adverse events between treatment groups, including among infants <1 year.[166a] Several observational studies of oseltamivir phosphate treatment for children younger than 1 year of age have documented symptom profiles during treatment similar to that reported for older children.[166–169]

Indications for Antiviral Treatment

Treatment of children with influenza virus infection should be based on the severity of disease, underlying medical conditions, and time since symptoms started. Empiric treatment is recommended for all people with suspected or confirmed influenza requiring hospitalization and for persons with progressive or complicated illness, regardless of previous health or vaccination status.[144,163] Empiric antiviral therapy also is recommended for people who are at a higher risk for influenza complications, such as children with underlying medical conditions, pregnant women, and children younger than 5 years of age (Box 229.2).[144]

Box 229.2

People at Higher Risk for Influenza Complications

Children <5 years of age, particularly children <2 years of age

Adults ≥65 years of age

Those with the following underlying medical conditions: chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, hematologic (including sickle cell disease), neurologic, neuromuscular, or metabolic (including diabetes mellitus) disorders

Those with immunosuppression caused by medications or underlying medical conditions (including HIV infection)

Women who are pregnant or within 2 weeks after delivery

Those <19 years of age who are receiving long-term aspirin therapy

American Indians and Alaskan Natives

Adults who are morbidly obese (body mass index ≥40)

Residents of nursing homes and other chronic care facilities

Antiviral treatment should be started as soon as possible after illness onset. Early initiation of treatment for severely ill children has been associated with reduced morbidity and mortality rates in some observational studies.[152,154] Empiric treatment often is necessary, and initiation should not be delayed while awaiting confirmatory diagnostic test results. Regardless of the initial test results, patients should continue to receive antiviral treatment until an alternative diagnosis can be established.[144] Treatment of severely ill patients, such as those who require hospitalization, is recommended regardless of illness duration. Several studies conducted among adults have shown that hospitalized patients benefit from treatment, even when it is initiated more than 48 hours after illness onset.[170,171]

Antiviral Resistance

Resistance to the adamantane compounds occurs as a result of mutations in the gene encoding the M2 protein, and resistance to the NA inhibitors occurs as a result of mutations in the HA or NA genes. Starting with the 2005–2006 influenza season, widespread adamantane resistance was observed among circulating influenza A (H3N2) viruses.[134] From the emergence of the 2009 H1N1 virus through May 2014, most influenza A and B viruses tested were resistant to the adamantanes but were sensitive to oseltamivir, zanamivir, and peramivir.[172] Oseltamivir-resistant 2009 H1N1 viruses have been detected sporadically, frequently in association with the *H275Y* mutation, and they have been associated with subtherapeutic treatment with oseltamivir in some instances.[173]

The emergence and rapid evolution of antiviral resistance among circulating influenza strains necessitates careful monitoring of local influenza surveillance data to determine which influenza strains are circulating and the prevalence of antiviral resistance among circulating strains. Influenza antiviral treatment strategies should be reassessed frequently based on local influenza virus circulation patterns.

Special Considerations

Immunocompromised Hosts

Immunocompromised hosts frequently acquire infection through nosocomial transmission, and they can shed virus for extended periods, especially if T-lymphocyte function is compromised.[60,174–177] Influenza A and B cause substantial morbidity and mortality rates for recipients of solid-organ and hematopoietic stem cell transplants; fatal pulmonary and neurologic syndromes have been reported.[176,178,179] Influenza-associated hemophagocytic syndrome has been reported for children with acute leukemias.[180] Guidelines for the prevention of influenza in hematopoietic stem cell transplant recipients have been published.[181]

Development of influenza viruses resistant to antiviral medications in immunocompromised patients exposed to antiviral medications is reported.[182,183] Influenza immunization is recommended by the American Society of Transplantation for recipients of solid-organ transplants before and after transplantation; if transplant recipients receive influenza vaccine soon after transplantation, revaccination 3 to 6 months after transplantation, when the immune response to vaccine is improved, may be warranted if still within the influenza season.[184]

Human Immunodeficiency Virus Coinfection

Some studies suggest that people infected with human immunodeficiency virus (HIV) have an increased susceptibility to influenza virus infection compared with the general population.[185,186] Children with HIV infection also may have prolonged virus shedding.[185] Influenza vaccination with trivalent inactivated vaccine (TIV) has a similar safety profile in HIV-infected children and HIV-uninfected children.[187] Vaccination with TIV produces adequate antibody responses in HIV-infected children receiving antiretroviral therapy, although antibody responses may be lower than those seen in healthy age-matched children, and responses are inversely correlated with the degree of immunosuppression.[187–191]

Annual influenza vaccination is recommended for all HIV-infected people in the US.[17] Because immune responses to influenza vaccination may be suboptimal in some children with HIV infection, influenza vaccination also is recommended for those who live with or care for HIV-infected children.[17]

Pregnancy

Although no evidence supports influenza as a teratogen or a cause of abortion, influenza during pregnancy may increase the risk of adverse infant outcomes, such as being born with a low birth weight and being small for gestational age.[193] Risk of hospitalization with influenza among pregnant women increases with gestational age, and women in the third trimester of pregnancy are hospitalized at a rate comparable with that of nonpregnant women with high-risk medical conditions.[194,195] Influenza pneumonia is associated with high morbidity and mortality rates for pregnant women.[196]

Influenza vaccination remains the primary strategy for reducing influenza complications among pregnant women.[17] Risk for influenza complications among pregnant and early postpartum women has emphasized the need for empiric antiviral treatment of any pregnant woman with suspected influenza.

Prevention

Vaccine

Two types of influenza vaccines are licensed for use in children in the US: an injectable inactivated influenza virus vaccine (IIV) and a live, attenuated inhaled vaccine (LAIV). A third type of vaccine, a recombinant protein vaccine (RIV) administered as an injection, also is FDA approved but not yet available for use in children. Inactivated virus vaccines are available as trivalent (IIV3) or quadrivalent (IIV4) preparations, whereas all live, attenuated vaccines in the US are now quadrivalent (LAIV). The IIV3s contain three vaccine strains selected to match the strains considered most likely to circulate in the upcoming influenza season: an influenza A (H1N1), an influenza A (H3N2), and an influenza B/Yamagata or influenza B/Victoria strain; quadrivalent preparations contain strains from both influenza B lineages.

In the US, influenza vaccines are made through three types of production technology: egg based, cell culture based, and recombinantly expressed proteins. The egg-based and cell culture–based technologies use vaccine strains initially grown in chicken eggs, whereas recombinant technology does not require egg-grown vaccine or use chicken eggs in the production process.

The US Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends influenza immunization annually for all persons at least 6 months of age. Immunization is particularly important for people at increased risk for severe influenza, including children younger than 5 years of age, people 50 years of age or older, those with chronic underlying medical conditions or immunosuppressive conditions, children receiving chronic aspirin therapy, women who are or will be pregnant during the influenza season, residents of long-term care facilities, American Indians and Alaska Natives, and people who are morbidly obese.[17] Household contacts and caregivers (including healthcare personnel, homecare providers, and employees of assisted-living and long-term care facilities) of people at increased risk for severe influenza also should be vaccinated.[17]

Immunization of all healthcare personnel is recommended by the ACIP, and mandatory immunization of healthcare personnel is recommended by the Infectious Diseases Society of America and the American Academy of Pediatrics.[197,198] Immunization of close contacts of children younger than 6 months of age is particularly important because these children cannot be immunized with currently licensed vaccines. Coverage in all groups, including healthcare personnel and young children, remains below levels that are likely to reduce substantially the impact of annual influenza epidemics.[192]

School-aged children often have the highest attack rates of influenza and play a key role in the introduction and transmission of influenza viruses in communities.[71,199–201] Observational studies and several randomized trials in which immunization of children was associated with reductions in influenza or respiratory illness among their household contacts or those living in the same community provide support for a universal recommendation for immunization of children.[202–205]

The efficacy of influenza vaccines depends on the age of the vaccine recipient, closeness of antigenic match between the vaccine strains and epidemic strains, and the end points used for the measurement of efficacy. Clinical efficacy studies that use laboratory-confirmed influenza as an end point have higher estimates of protection than effectiveness studies that use clinical illness end points. Currently available influenza vaccines are challenging to manufacture quickly and do not provide reliable protection against strains that are antigenically different from the vaccine strain. The continuous antigenic changes that occur among influenza viruses result in the need for annual revaccination. Efforts to improve influenza vaccines are an active area of research, including development of more immunogenic vaccines that can be manufactured in shorter timeframes and universal influenza vaccines that can protect against drifted strains over multiple seasons.[206–208]

Vaccine for Children With Egg Allergies

Specific guidelines exist for giving influenza vaccine to children with a history of egg allergy.[17] Only IIVs are recommended for children with egg allergy because data on the use of LAIV in this population are limited. Children with any allergic reaction to eggs involving symptoms other than hives should be vaccinated under the supervision of a health care provider experienced in managing severe allergic conditions.

Inactivated Vaccine

Inactivated seasonal influenza vaccines available in the US are split virus or virus subunit vaccines, and they are considered interchangeable when given in the standard doses. The immunogenicity of IIV is inconsistent in infants younger than 6 months of age.[209–211] IIVs are licensed for use in people at least 6 months of age.

Seroresponse rates increase with increasing age, reaching 70% to 100% among adolescents. However, immunologic priming is important for a response to IIV, and a single dose of vaccine is ineffective in inducing immunity and protection in children lacking previous experience with the matching influenza type or subtype.[212] Young children require several years of exposure to influenza epidemics or two doses of vaccine to ensure a reliable response to all vaccine antigens after the administration of an inactivated vaccine.[213,214] Two doses of IIV administered 4 or more weeks apart are recommended for children younger than 9 years of age during their first season of influenza immunization.[17]

In a large, randomized, placebo-controlled trial that evaluated IIV in children 1 to 15 years of age, vaccine efficacy ranged from 77% to 91%.[215] Other observational studies have estimated lower vaccine effectiveness among children.[216–220] The incidence of AOM in two studies of IIV and one study of LAIV was lower among influenza vaccine recipients than among unimmunized children.[221–223] However, a randomized, placebo-controlled study of IIV in children 6 to 24 months of age failed to show decreases in the incidence of AOM or duration of middle ear effusion in vaccine recipients.[224]

Fewer data are available on vaccine efficacy and effectiveness in children with underlying chronic medical conditions. Among children with asthma, IIV has been safe and efficacious in preventing influenza, but studies of the effectiveness of influenza vaccination to prevent acute asthma exacerbations have produced mixed results.[225–230] Among children with HIV infection, data on IIV efficacy is limited largely to studies evaluating immunologic outcomes. Several studies have documented that IIV is at least moderately immunogenic in children with HIV infection, although immune responses to vaccine are inversely correlated with the degree of immunosuppression.[187,188,191] A randomized, placebo-controlled trial evaluating IIV efficacy against clinical influenza among South African children 6–59 months of age with HIV infection found that IIV was 18% efficacious during a year in which circulating influenza viruses had drifted from the vaccine strain.[190]

Vaccination of pregnant women with an IIV provides protection to their infants, presumably through passive transfer of antibodies against influenza.[231,232] Vaccination of pregnant women with IIV3 was 63% effective in preventing laboratory-confirmed influenza among infants of vaccinated women through 6 months of age in a randomized, controlled trial and resulted in a 41% reduction in laboratory-confirmed influenza among infants through 6 months of age in a prospective cohort study.[233,234]

In 2009, a higher-dose IIV (i.e., fourfold increase in vaccine antigen) was licensed in the US for people 65 years of age or older and has demonstrated superior immunogenicity and effectiveness.[17,235] In 2011, the FDA licensed a reduced-dose (i.e., 9-μg of HA per strain) intradermal, inactivated vaccine for use in people between the ages of 18 and 64 years.[17] The intradermal vaccine uses a 1.5-mm microneedle to deliver vaccine consistently into the dermis, which is heavily populated with dendritic cells involved with antigen presentation. In a randomized trial, reduced-dose intradermal vaccine elicited similar humoral and cell-mediated immune responses compared with intramuscular vaccine in healthy adults.[236]

Live, Attenuated Vaccines

Live, attenuated influenza vaccines in which six internal protein genes of a temperature-sensitive, attenuated, cold-adapted parent influenza virus are combined with wild-type HA and NA genes are licensed for use in healthy, nonpregnant people between 2 and 49 years of age.[17] However, observational studies found that LAIV had low to no effectiveness against the predominant circulating influenza strains among children 2 to 17 years in the US during the 2013 to 2016 influenza seasons. As a result, the ACIP recommended against the use of LAIV during the 2016 to 2017 influenza season.[17,236a,237]

Many studies have shown that LAIV is safe for healthy, school-age children and adolescents.[223] In the largest randomized, controlled trial conducted among children younger than 6 years of age, those with medically diagnosed or treated wheezing within 42 days before enrollment or with a history of severe asthma were excluded.[237a] Using a prespecified definition, the rate of medically significant wheezing was no greater among LAIV recipients than IIV recipients among children 24 to 59 months of age, but it occurred more frequently among LAIV recipients 6 to 23 months of age. However, a significantly increased risk of wheezing was observed among children 18 to 35 months of age in another study.[238]

In a pooled analysis of 20 studies evaluating LAIV compared with placebo or IIV in children 2 to 17 years of age, children 24 to 35 months of age who received LAIV did not have higher rates of wheezing.[239] Based on these observations, LAIV is not approved for use in children younger than 24 months old, and the ACIP recommends against the use of LAIV in children 2 to 4 years of age with a history of wheezing during the preceding 12 months or children of any age with asthma.[17]

Shedding of vaccine strain virus has been documented in children who have received LAIV; when genotype analysis was performed, shed virus retained the attenuated phenotype.[240–242] The frequency of transmission of LAIV from immunized young children to unimmunized contacts has been estimated to be less than 2%, and it is likely lower among older children and adults who shed less virus.[240,241] Transmission of vaccine virus from immunized people to unimmunized contacts has not been shown to cause significant illness.[241] LAIV virus is shed for a shorter duration and at lower titer than wild-type influenza virus.[243] LAIV should not be given while the recipient is receiving influenza antiviral medication because antivirals decrease influenza viral replication and may interfere with the immune response to LAIV. People who receive influenza antiviral medications during the 2 days before to 14 days after receiving the LAIV should be reimmunized after cessation of antiviral therapy.[17]

People who receive LAIV develop mucosal immunity, which is challenging to measure. Clinical studies have demonstrated that LAIV has excellent efficacy against influenza during most seasons, particularly among children. In one randomized, controlled trial comparing LAIV with placebo in children, two doses of LAIV were 94% effective against culture-confirmed influenza, and a single dose was 89% effective during a season when the vaccine strains were well matched against circulating strains and 86% effective during a season when the predominant circulating strain had drifted from the vaccine strain.[244,245] The efficacy of LAIV against laboratory-confirmed seasonal influenza in young children in other randomized trials has ranged from 52% to 89%.[244–246]

The safety, immunogenicity, and efficacy of LAIV and IIV have been compared in several studies.[237a,248–251] Both vaccines are well tolerated and effective but elicit substantially different immune responses.[250,251] In randomized, controlled comparative trials enrolling young children, vaccination with LAIV was more effective than IIV against laboratory-confirmed influenza, regardless of the match between circulating strains and vaccine strains, and it provided greater cross-protection during seasons when vaccine strains were not well matched against circulating influenza virus strains.[248]

In a study comparing immune responses to a 2-dose sequence of IIV, LAIV, or a combination of the two vaccines in children between 6 and 35 months of age, both vaccines induced similar humoral antibody responses, but only LAIV induced cell-mediated responses thought to be important for heterosubtypic immunity.[252] In contrast, in several randomized, placebo-controlled studies comparing LAIV and IIV in healthy young adults, IIV was more efficacious.[253–255] In a single study conducted among adults, LAIV was more effective in those who had never received influenza vaccine in the past.[256]

Chemoprophylaxis

If given before or shortly after influenza virus exposure, chemoprophylaxis with an influenza antiviral agent can effectively prevent symptomatic influenza virus infection. Oseltamivir postexposure chemoprophylaxis (PEP) in household contacts of those with influenza has been 68% to 89% effective in preventing laboratory-confirmed influenza when given soon after exposure.[257,258] Several studies have documented similar efficacy for zanamivir when it is given as PEP.[259,260]

In most situations, counseling patients about signs and symptoms of influenza and encouraging early treatment if signs or symptoms develop constitute a preferable alternative to chemoprophylaxis for people with a suspected exposure to influenza virus. Clinical judgment based on consideration of the patient's age, severity of underlying illness, ability to comply with a chemoprophylactic regimen, and access to medical care should be used when considering PEP. PEP is considered for those at high risk for severe influenza who have not been vaccinated or have received vaccine less than 14 days before exposure.[261]

Chemoprophylaxis should be given for 10 days and within 48 hours after the time of exposure.[261] Occasionally, extended periods of prophylaxis are indicated for patients who cannot be immunized.[262] The choice of antiviral agent used for chemoprophylaxis should be guided by local surveillance data on antiviral resistance when available. Influenza virus infection can occur in those receiving antiviral chemoprophylaxis, and sporadic cases of antiviral-resistant influenza virus infection have been identified in people taking chemoprophylaxis.[173,258,262,263] Clinicians should advise patients taking chemoprophylaxis to seek care at the first signs of respiratory illness, and providers should consider antiviral-resistant influenza virus as a potential cause in these instances.

Zoonotic Influenza

Influenza viruses infect many animal species in addition to humans. Interspecies transmission has been documented, including human infections with avian and swine influenza viruses. Human infection with novel or nonhuman influenza A virus strains, including influenza A viruses of animal origin, is a notifiable disease in the US.[264]

Sporadic cases and clusters of human infection with avian viruses with HA subtypes H5, H6, H7, H9, and H10 prove that avian influenza A viruses can be transmitted directly to humans without passage through an intermediate host and without acquiring human influenza gene segments by genetic reassortment.[265] The first case of human infection with an avian influenza A H5N1 virus was identified in 1997 in a child in Hong Kong, who died as a result of the infection.[266] A few months later, 17 additional cases occurred with 5 additional deaths.[267] The 1997 outbreak ended, but progenitors of the Hong Kong H5N1 viruses continued to circulate in avian species in the region. In late 2002, outbreaks of highly pathogenic H5N1 avian influenza were reported in 10 countries in Asia and human cases were reported in Vietnam and Thailand.[268,269] Since then, H5N1 viruses have spread to other countries in Asia, Europe, and Africa, and more than 800 cases of human infection and more than 400 deaths have been reported (http://www.who.int/csr/disease/avian_influenza/en).

Other avian influenza viruses have emerged and caused outbreaks among humans. Most notably, the avian H7N9 virus has led to more than 800 cases of human infection predominantly linked to bird exposure at live bird markets in China since 2013.[270,271] In 2015, outbreaks of several subtypes of avian influenza viruses, including H5N1, H5N2, and H5N8, among birds in the US were identified, highlighting the potential threat of human infection with avian influenza viruses in North America.[272,273] Guidance for infection control, testing, and influenza antiviral chemoprophylaxis for people in the US exposed to birds with suspected or confirmed avian influenza virus infection is available (http://www.cdc.gov/flu/avianflu).

The incubation period for human cases of avian influenza virus infections ranges from 2 to 6 days, but longer incubation periods have been reported.[271,274] Most patients with avian influenza virus infection have a history of contact with sick poultry, but there are instances of probable person-to-person transmission among family clusters with close contact.[271,275,276] Although most cases have febrile respiratory illnesses (sometimes with dyspnea), there have been reports of atypical infections, including infections in two children who had diarrhea and coma without respiratory tract symptoms.[277–279]

Laboratory findings include lymphopenia, thrombocytopenia, and in some cases, abnormal hepatic transaminase levels.[280–282] Reported complications include progression to acute respiratory distress syndrome, shock, and renal failure.[280,282–285] The diagnosis of avian influenza virus infections is based on molecular methods.[286]

In a review of 308 persons infected with H5N1, oseltamivir treatment initiated up through 6 to 8 days after symptom onset reduced the mortality rate by 49%.[287] Although treatment of avian influenza virus infection with oseltamivir provides a survival benefit, the case-fatality rate for treated patients remains high. Resistance to oseltamivir or amantadine has been reported for H5N1 viruses. H7N9 viruses are resistant to adamantanes, and sporadic resistance to oseltamivir and zanamivir has been reported.[270,288–291]

Sporadic cases and clusters of human infection with swine influenza viruses have been reported in the US and elsewhere since 1958. They include infection with classic swine influenza viruses and triple-reassortant swine influenza viruses containing genes from human, avian, and swine influenza viruses.[292] In 2011, sporadic cases of human infection with a newly identified swine-origin triple-reassortant influenza A (H3N2) virus containing genes from a swine-origin A (H3N2) virus known to be circulating in North American pigs and the matrix gene from the 2009 H1N1 virus were identified, including a case cluster in which limited human-to-human transmission might have occurred.[293,294] Most patients with swine influenza virus infection were exposed during participation at agricultural fairs and have had mild, self-limited illnesses that were clinically indistinguishable from seasonal influenza, although severe and fatal cases also have been reported.[292,295]

The incidence of human infection with swine influenza viruses is unknown because testing for influenza viruses is not always conducted for patients with influenza-like illness. However, serologic studies suggest that these infections might occur more frequently among persons with occupational exposure to swine and their close contacts.[296,297]

Swine influenza virus infections should be considered in the differential diagnosis of patients with respiratory illness and recent swine exposure.[298] Avian influenza virus infections should be considered in the differential diagnosis of those with respiratory illness and recent contact with sick or dead birds.[299] If swine or avian influenza virus infection is suspected, clinicians should obtain a nasopharyngeal swab, nasal aspirate or wash, or swabs from two sources combined into one tube of viral transport media from the patient and contact the local health department to facilitate testing.

Pandemic Influenza

The introduction with subsequent global spread in humans of a novel influenza A virus is referred to as *antigenic shift*. The prerequisites for a pandemic are isolation from humans of a novel influenza virus to which the general population has little or no immunity, ability of the virus to replicate and cause disease in humans, and sustained and efficient transmissibility of the virus from person to person.[300]

Novel influenza viruses with pandemic potential can arise through reassortment of gene segments among avian, swine, or human influenza viruses in humans or an intermediate host or can be wholly avian or swine influenza A viruses that cross the species barrier and directly infect humans.[301] As demonstrated in 2009, a pandemic can result if a virus emerges with antigenic characteristics that are novel to most humans; an entirely new HA gene is not necessarily required.[41]

The history and biology of influenza viruses indicate that future influenza pandemics are inevitable. However, the timing of a pandemic, the subtype that will cause it, and the impact of the pandemic cannot be predicted. Specific measures for the control of influenza pandemics include vaccines and antiviral drugs. Two inactivated avian influenza vaccines, including adjuvanted and unadjuvanted influenza A/H5N1 vaccines, are licensed in the US.[302] The US Department of Health and Human Services maintains a stockpile of avian influenza vaccines and the two currently licensed classes of antiviral drugs, adamantanes and NA inhibitors.[303] The US government pandemic preparedness plan is available at www.pandemicflu.gov.

Key Points

Influenza Virus Infections

Microbiology

- Three antigenic types of influenza viruses are recognized: A, B, and C.
- The surface proteins hemagglutinin (HA) and neuraminidase (NA) are the major targets of the protective immune response. Minor changes in these surface glycoproteins are responsible for the ability of influenza viruses to evade immunity acquired from infection in previous seasons and cause annual epidemics of respiratory illness.
- The emergence of influenza A viruses with novel HAs that are antigenically distinct from previously circulating influenza A viruses has resulted in four influenza pandemics in 1918, 1957,

1968, and 2009.

Epidemiology

- Among children, influenza-associated hospitalization rates are highest among young children, especially infants younger than 6 months of age.

- People at increased risk for severe seasonal influenza include children younger than 5 years of age, people 65 years of age or older, those with chronic medical conditions, pregnant women, residents of long-term care facilities, American Indians and Alaska Natives, and people who are morbidly obese.

- Annual influenza immunization is recommended in the US for all those 6 months or older. Infants younger than 6 months can be protected by vaccinating the pregnant mother and other members of the household.

Diagnosis

- Clinical signs and symptoms often are not distinctive; laboratory testing is the only reliable way to distinguish influenza from other respiratory infections.

- Real-time reverse transcription polymerase chain reaction (RT-PCR) is the gold standard for diagnosis. Virus culture is less sensitive but yields isolates that can be typed, subtyped, and characterized antigenically and genetically.

- Rapid diagnostic tests have various degrees of sensitivity and specificity. During periods when influenza viruses are known to be circulating in the community, a patient with a negative rapid test result still may have influenza, and clinicians should use clinical judgment to decide whether to initiate antiviral therapy or obtain additional diagnostic testing.

Treatment

- Immediate empiric treatment is recommended for those with suspected influenza requiring hospitalization or with progressive or complicated illness.

- Treatment is recommended for people with chronic medical conditions, pregnant women, and children younger than 5 years of age.

- Two classes of antiviral drugs are available: the adamantanes (i.e., rimantadine and amantadine) and the neuraminidase inhibitors (i.e., oseltamivir, zanamivir, and peramivir).

- In recent years, neuraminidase inhibitors are the mainstay of treatment.

- Local surveillance and prevalence of antiviral resistance should be used to guide antiviral treatment strategies.

RNA Viruses: Arenaviridae and Filoviridae

OUTLINE

230 Filoviruses and Arenaviruses

230

Filoviruses and Arenaviruses

Margot Anderson, Daniel G. Bausch

The Viruses

Viruses of the families Filoviridae and Arenaviridae are composed of single-stranded RNA in lipid envelopes.[1–3] The Filoviridae comprise five pathogenic species of Ebola virus and one Marburg virus (Table 230.1). Arenaviruses are taxonomically divided into Old World (i.e., Africa) and New World (i.e., Americas) viruses.

TABLE 230.1

Filoviruses and Arenaviruses Known to Cause Human Disease

Virus	Disease	Principal Reservoir or Vector	Geographic Distribution of Disease	Annual Cases	Disease-to-Infectio Ratio
FILOVIRIDAE					
Ebola	Ebola virus disease or Ebola HF	Fruit bat?	Sub-Saharan Africa, Philippines[b]	—[a]	1 : 1
Marburg	Marburg virus disease or Marburg HF	Fruit bat (Egyptian fruit bat [*Rosettus aegyptiacus*])	Sub-Saharan Africa	—[a]	1 : 1
ARENAVIRIDAE[c]					
Old World					
Lassa	Lassa fever	Rodent (multimammate rat [*Mastomys*	West Africa	30,000–50,000	1 : 10

		natalensis])			
Lujo[d]	Lujo HF	Unknown; presumed rodent	Zambia	Unknown	Unknow
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis	Rodent (house mouse [*Mus musculus*]); transmission from pet rodents also documented	Worldwide	Unknown; infection probably frequent but underrecognized	3 : 10
Dandenong[e]	Dandenong fever	Unknown: presumed rodent	Unknown: Balkan Peninsula?	Three cases recognized to date	Unknow
ARENAVIRIDAE					
New World					
Junin	Argentine HF	Rodent (corn mouse [*Calomys musculinus*])	Argentine pampas	<50	1 : 1.5
Machupo	Bolivian HF	Rodent (large vesper mouse [*Calomys callosus*])	Beni Department, Bolivia	<50	1 : 1.5
Guanarito	Venezuelan HF	Rodent (cane mouse [*Zygodontomys brevicauda*])	Portuguesa State, Venezuela	<50	1 : 1.5
Sabiá[f]	Brazilian HF	Unknown; presumed rodent	Rural area near Sao Paulo, Brazil?	—[e]	1 : 1.5
Chapare[g]	Chapare HF	Unknown; presumed rodent	Cochabamba, Bolivia	Unknown	Unknow

[a] Although some endemic transmission of the filoviruses (i.e., Ebola > Marburg) occurs, these viruses have most often been associated with outbreaks. Until the 2013–2016 Ebola virus outbreak in West Africa, in which more than 28,000 cases occurred, filovirus outbreaks typically had less than 100 cases, with 425 cases being the largest previous outbreak.

[b] Five species of Ebola virus are known, with the following mean case-fatality ratios: Ebola Zaire, 76%,;Ebola Sudan, 55%; Ebola Bundibugyo, 37%; Ebola Tai Forest, 0% (only 1 recognized case), and Ebola Reston, 0% (not pathogenic to humans).[89] All are endemic to sub-Saharan Africa, with the exception of Ebola Reston virus which is found in the Philippines.

[c] In addition to the arenaviruses listed in the table, Flexal, Pirital, and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been detected in sick people in California, but its role as a pathogen has not been clearly established.

[d] Discovered in 2008 in an outbreak of 5 cases (4 fatal) in South Africa. The index case came to South Africa from Zambia.

[e] Discovered in 2009 in a cluster of 3 fatal transplant-related cases that occurred in Australia. The donor died of cerebral hemorrhage 10 days after returning to Australia

from a 3-month visit to the former Yugoslavia, where he had traveled in rural areas.

[f] Discovered in 1990. Only 3 cases (1 fatal) of Sabiá virus infection have been identified, 2 of them from laboratory accidents.

[g] Discovered in 2003 in a small outbreak in Cochabamba, Bolivia. Chapare virus was isolated from a fatal case, but few other details from the outbreak have been reported.

HF, hemorrhagic fever.

Along with viruses from the Bunyaviridae and Flaviviridae families (see Chapters 218 and 219), filoviruses and arenaviruses are the principal causative agents of hemorrhagic fever (HF). Viral HF is an acute and sometimes severe systemic illness that classically involves fever, a constellation of initially nonspecific signs and symptoms, potentially severe volume loss through diarrhea and vomiting, and a propensity for shock and bleeding. The exception is lymphocytic choriomeningitis virus (LCMV), an Old World arenavirus that has become disseminated worldwide. LCMV infection is classically associated with febrile illness and central nervous system (CNS) disease.[4] A variant of LCMV, Dandenong virus, associated with severe disease in transplant recipients, was discovered in 2009.[4a] Many of these viruses are considered potential bioweapons.[5]

Epidemiology

Maintenance in Nature and Transmission to Humans

Filoviruses and arenaviruses are zoonotic, with the endemic area for each virus restricted by the distribution of its animal reservoir.[1,2,4] With the exception of Lassa virus and the 2013–2016 epidemic of Ebola virus in West Africa (>28,000 cases), human infection is uncommon.

Humans play no role in maintenance of the virus in nature. Fruit bats are thought to be the filovirus reservoir. Pathogenic arenaviruses are maintained in rodents, with strict pairing between the specific virus and animal reservoir (see Table 230.1).[4,6,7] Miners, spelunkers, forestry workers, and others with exposure to environments where bats typically roost are at risk of filovirus infection.[8–10] The rodents that transmit Lassa and Machupo viruses and LCMV commonly invade domestic environments, whereas the reservoirs for Junín and Guanarito viruses typically inhabit agricultural fields, wood lots, or other rural habitats.[4]

Transmission to humans usually occurs through inadvertent exposure to animal excreta or saliva or, in some cases, blood and other body fluids when the animals are hunted and butchered.[1–4] Nonhuman primates, especially gorillas and chimpanzees, and other wild animals can serve as intermediate hosts for filoviruses.[11–13] These animals are presumably infected by exposure to bats and develop severe and usually fatal disease similar to human HF. Because the HF viruses are rapidly inactivated by heating, infection likely occurs through exposure during preparation rather than by consumption of cooked meat. LCMV has been transmitted to humans through contact with infected laboratory mice and cell lines and by pet rodents, especially hamsters.[14]

Human-to-Human Transmission

Although attack rates usually are low (15% to 20%, even for Ebola Zaire virus, which probably is the most transmissible), secondary human-to-human transmission does occur (see Table 230.1), as seen most dramatically in the 2013–2016 Ebola Zaire virus outbreak in West Africa.[15–17] Large outbreaks typically are fueled by nosocomial transmission in resource-poor regions, where basic infection control practices cannot be maintained.[17a] Infectivity parallels the clinical state, and people are most infectious late in the course of severe disease.[18] There is no evidence of transmission during the incubation period.

Transmission occurs through direct contact with blood or body fluids and probably occurs through oral or mucous membrane exposure, most often in the context of providing care to a sick family member (i.e., community exposure) or patient (i.e., nosocomial transmission), or by participation in burial rituals that involve washing and touching corpses.[19] Transmission through breast milk and congenital transmission have been documented.[20] Infection through fomites cannot be excluded but is probably not common unless the object is obviously contaminated with blood or body fluids.[20,21] Sexual transmission from virus persistence in the semen has been identified more than 1 year after recovery from acute disease.[22]

Although infectious aerosols have been artificially produced in the laboratory, which is a concern because of the potential for their use in biowarfare, epidemiologic and limited laboratory-based data do not suggest aerosol transmission between humans in natural settings.[15,19,23–26]

Pathobiology

After inoculation onto mucous membranes or deposition in the lungs and initial replication in local tissues, virus migrates to regional lymph nodes and ultimately through the blood to a broad range of tissues.[1–3,27] The liver, endothelium, and adrenal glands appear to be particularly important targets. The CNS is especially affected in LCMV and New World arenavirus infections.[3]

Microvascular instability and impaired hemostasis are the hallmarks of viral HF.[1–3] Impaired hemostasis can entail endothelial cell, platelet, or coagulation factor dysfunction. Disseminated intravascular coagulopathy (DIC) may occur. Because bleeding has been seen in a minority of HF cases, renaming of some of the diseases has been suggested to de-emphasize the hemorrhagic component. For example, Ebola HF is now commonly referred to as Ebola virus disease (EVD). Rather than exsanguination, severe disease results from an inflammatory and vasoactive process consistent with the systemic inflammatory response syndrome (see Chapter 11) and severe fluid loss from diarrhea, vomiting, and fever resulting in insufficient effective circulating intravascular volume, cellular dysfunction, and multiorgan system failure.[27,28] Cardiac inotropy can be inhibited, especially in cases of Lassa fever, and pericardial and pleural effusions have been seen when radiographic equipment is available.[29,30] In severe disease, viremia remains unchecked, and there is little or no antibody response.[18] Inflammatory cell infiltrates at sites of infection also are mild.[31]

Immune cell activation is the fundamental process in the pathogenesis of LCMV, although without the same effects on endothelial cell function and hemostasis as in HF.[3] CNS involvement in LCMV typically occurs 1 or 2 weeks after disease onset, after virus has cleared from the bloodstream, and it is thought to be immune mediated, although virus can still be recovered from the cerebrospinal fluid (CSF) at this time.[3]

Clinical Manifestations

Viral Hemorrhagic Fever

Filovirus and arenavirus infections are seen in both sexes and all age groups, with a spectrum from asymptomatic infection (especially for arenaviruses) to rapidly fatal disease.[8,32–39] It is usually not possible, especially at disease onset, to distinguish the specific virus cause by clinical manifestations. The syndrome produced by the New World arenaviruses is usually collectively referred to as *South American HF*.

After an incubation period of 8 to 10 days (range, 3–21 days), patients typically have nonspecific signs and symptoms, including fever, general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, lumbosacral pain, and dizziness. Hiccups can occur early in EVD. The pharynx may be erythematous or exudative in Lassa fever, sometimes leading to misdiagnosis of streptococcal pharyngitis. Gastrointestinal signs and symptoms ensue rapidly and include nausea, vomiting, epigastric and abdominal pain, abdominal tenderness, and diarrhea, which in EVD can be voluminous.[37,38,40,41] Misdiagnosis as acute appendicitis or another abdominal emergency sometimes occurs. A dry cough with a few scattered rales is common, but prominent pulmonary symptoms are uncommon early in the course of the disease. Jaundice is not typical and suggests a different diagnosis.

Clinical manifestations for a subset of patients, especially those with filovirus infections, progress to vascular instability marked by conjunctival injection (not accompanied by itching, discharge, or rhinitis), facial flushing, edema, bleeding, hypotension, shock, and proteinuria. The likelihood of clinically discernible hemorrhage is highest for filovirus infections and the South American HFs, although it still is seen in a minority of patients. Hematemesis, melena, hematochezia, metrorrhagia, petechiae, purpura, epistaxis, and bleeding from the gums and venipuncture sites can develop, but hemoptysis and hematuria are uncommon (Fig. 230.1). Bleeding rarely occurs in the first few days of illness. Swelling of the face and neck is sometimes seen in Lassa fever, and Lujo HF is relatively specific to these diseases (see Fig. 230.1).[36] Extensive edema attributed to massive vascular leakage (i.e., swollen baby syndrome) has been described in children with Lassa fever.[42]

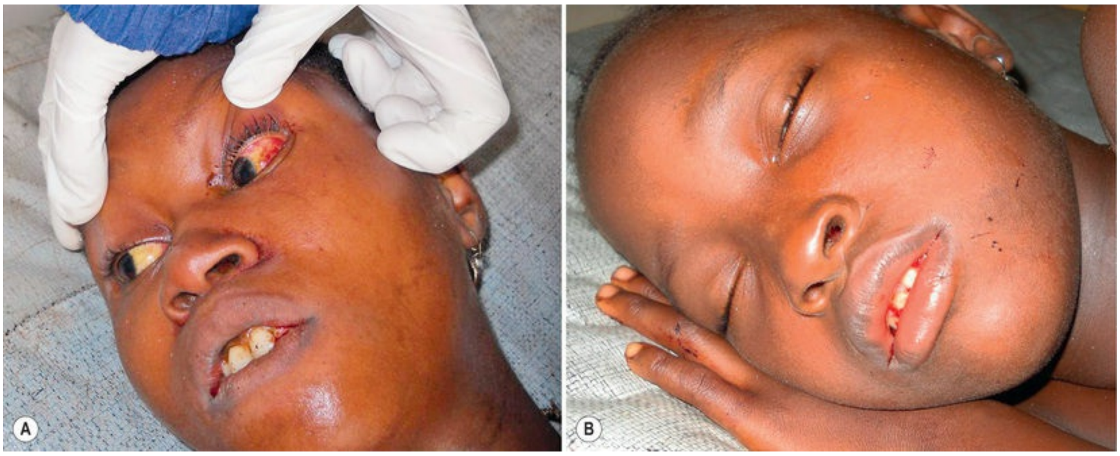

FIGURE 230.1 Subconjunctival hemorrhage, oral bleeding, and facial swelling in patients with Lassa fever. (Courtesy of Victor Lungay.)

Morbilliform, maculopapular, petechial, and ecchymotic rashes can occur. Maculopapular rash on the torso or face may be an early and relatively specific, although not sensitive, indicator of filovirus infection. For unclear reasons, rash typically occurs in light-skinned people with Lassa fever, but it is rare in dark-skinned people.

CNS manifestations, including disorientation, tremor, gait anomalies, convulsions, and hiccups, can occur in end-stage disease, especially in South American HF, particularly Argentine HF.[3] Renal insufficiency or failure is common. Pregnant women often come to medical attention because of spontaneous abortion and vaginal bleeding.[43–45] However, a few Ebola virus–infected pregnant women have had mild or atypical clinical manifestations, posing a diagnostic dilemma.[46]

Common clinical laboratory findings are summarized in Table 230.2. Radiographic and electrocardiographic findings usually are nonspecific and correlate with the physical examination findings.[47,48]

TABLE 230.2

Clinical Laboratory Tests and Characteristic Findings for Filovirus and Arenavirus Infections

Test	Characteristic Findings and Comments
Leukocyte count	Early: moderate leukopenia, sometimes with atypical lymphocytes Later: leukocytosis with left shift suggesting bacterial infection
Hemoglobin and hematocrit	Hemoconcentration
Platelet count	Mild to moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid-base perturbations, depending on fluid balance, renal function, and stage of disease
BUN and creatinine	Renal failure can occur late in disease.
Serum chemistries (AST, ALT, amylase, γ-glutamyl transferase, alkaline phosphatase, creatinine kinase, lactate dehydrogenase, lactate acid)	Usually increased, especially in severe disease; AST > ALT; lactate level >4 mmol/L (36 mg/dL) can indicate persistent hypoperfusion and sepsis
Sedimentation rate	Normal or decreased
Blood gas	Metabolic acidosis can indicate shock and hypoperfusion
Coagulation studies (PT, PTT, fibrinogen, fibrin split products, platelets, D-dimer)	DIC common in Ebola, Marburg, Lujo virus, and New World arenavirus infections
Urinalysis	Proteinuria common; hematuria seen occasionally; sediment can show hyaline-granular casts and round cells with cytoplasmic inclusions
Blood culture	Useful early to exclude viral HF if positive and later to evaluate for secondary bacterial infection; blood should be drawn before antibiotic therapy is instituted
Stool culture	Useful to exclude viral HF if positive for hemorrhagic bacillary dysentery
Thick and thin blood smears	Useful for the diagnosis of blood parasites (malaria and trypanosomes) and bacterial sepsis (meningococcus, *Capnocytophaga*, and anthrax); negative in viral HF unless coinfection
Rapid test, PCR, or other assay for malaria	Negative in viral HF unless coinfection with malaria
Febrile agglutinins or other assay for *Salmonella enterica* serotype Typhi	Negative in viral HF unless coinfection
Cerebrospinal fluid analysis	Usually normal in viral HF Lymphocytic choriomeningitis: protein moderately increased (50–150 mg dL); glucose normal or decreased; mononuclear pleocytosis up to 5000 cells/mm^3 (although neutrophils can comprise up to 25% of cells)

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; DIC, disseminated intravascular coagulation; HF, hemorrhagic fever; PCR, polymerase chain reaction; PT, prothrombin; PTT, partial thromboplastin time.

In fatal cases, death occurs about 8 to 10 days after onset of disease for the filoviruses and 10 to 14 days for arenaviruses. Shock, bleeding, neurologic manifestations, high levels of viremia, elevated levels of aspartate aminotransferase (>150 IU/L), and pregnancy, especially during the third trimester, are indicators of a poor prognosis. The mortality rate is especially high for children younger than 5 years of age.[36,38,40,49] Despite slightly improved survival of pregnant women during the 2013–2016 outbreak in West Africa, most pregnancies result in stillbirths or early neonatal death, with only one report of a child, who received various experimental therapies, surviving beyond the neonatal period.[45,45a] Rarely, women who were infected during pregnancy have survived acute EVD without aborting, only to experience a stillbirth of a macerated fetus in the subsequent weeks. The stillborn fetuses were confirmed to be positive for the virus by RT-PCR testing, despite no evidence of persistent Ebola virus in the mothers' blood. This finding is thought to result from the relative immune privilege of the intrauterine compartment during pregnancy and immaturity of the fetal immune system allowing viral persistence.

Lymphocytic Choriomeningitis Virus Infection

Many LCMV infections are asymptomatic or result in a nonspecific febrile illness, sometimes accompanied by photophobia.[50] After 7 to 14 days of illness and often after a brief period of defervescence, a spectrum of CNS manifestations ensue in some patients. They include aseptic meningitis (the most common) and fulminant encephalitis with cranial nerve palsies, abnormal reflexes, focal seizures, polyneuritis, flaccid paralysis, and papilledema. CNS symptoms also can occur without a recognized febrile illness. Rare manifestations and complications of LCMV infection include hydrocephalus, transverse myelitis, Guillain-Barré syndrome, hearing loss, arthritis, parotitis, orchitis, myocarditis, mucosal bleeding, and pneumonia.

Congenital infection has been associated with spontaneous abortion in early pregnancy and, when occurring later in pregnancy, with a variety of neurologic deficits, including psychomotor retardation, microcephaly and macrocephaly, ventriculomegaly, hydrocephalus, nonimmune hydrops fetalis, intracranial hemorrhage, chorioretinitis with visual loss, and seizures (Fig. 230.2).[51] Occasional LCMV and Dandenong virus infection in organ transplant recipients has resulted in a highly fatal syndrome, sometimes resembling viral HF.[52]

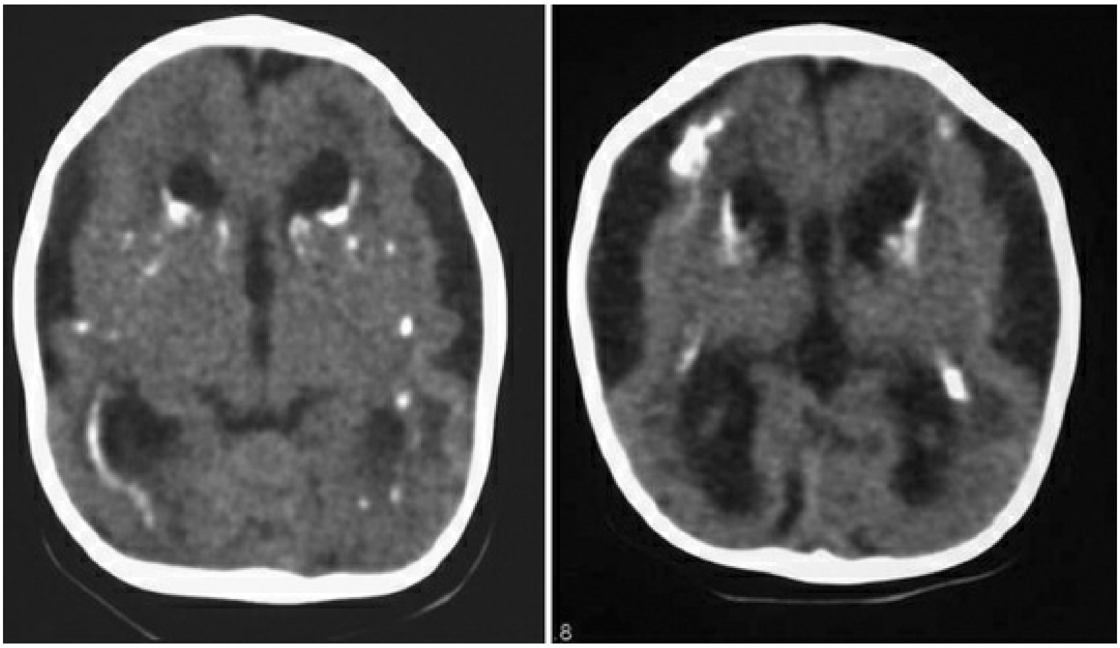

FIGURE 230.2 Computed tomography of a 5-month-old infant with profound developmental delay and chorioretinitis due to intrauterine lymphocytic choriomeningitis virus infection. Scans show microcephaly, lissencephaly, and calcifications that are periventricular, intracerebral, and over the convexities of the brain. The serum immunofluorescent antibody titer was greater than 1 : 1024. The mother had no known illness or exposure to rodents during pregnancy. (Courtesy of G.L. Rodgers and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Differential Diagnosis

The nonspecific presentation of people with filovirus and arenavirus infections leads to an extremely broad differential diagnosis that varies by geographic region but often includes malaria, typhoid fever, leptospirosis, rickettsial disease, and many other systemic febrile illnesses.[1–3] Clinicians should focus on making the general diagnosis of viral HF and then quickly seek laboratory support to confirm the syndrome and specific infecting virus. For LCMV with neurologic manifestations, the arboviral meningitides and herpes encephalitis must be ruled out.

A diagnosis of viral HF should be considered in patients with a clinically compatible syndrome who within 3 weeks before disease onset had any of the following risk factors:

- Resided in or traveled to areas where a HF virus is known or suspected to be endemic
- Possibly had direct contact with blood or body fluids of someone with a suspected or confirmed viral HF during their acute illness (includes healthcare personnel and those caring for family members at home or touching corpses at a funeral)
- Had contact with live or recently killed wild animals (especially bats, nonhuman primates, and rodents) in or recently arriving from an area where a HF virus is endemic
- Worked in a laboratory or animal facility where HF viruses are handled
- Had sex with someone recovering from a viral HF in the past year

Because viral HF is rare even in people possessing one of the risk factors, alternative diagnoses always should be sought aggressively, especially malaria and typhoid fever. Acts of bioterrorism must be considered if viral HF is seen in a patient without any of the risk factors, especially if there are clusters of cases.[5] All confirmed cases should be reported immediately to local, state, and federal health authorities.

Laboratory Testing

Prompt laboratory diagnosis is imperative. RT-PCR is the mainstay of diagnosis, with sensitivities and specificities usually higher than 90%.[18,53–56] A few rapid dipstick tests have been developed, but because these tests await thorough validation, results should be confirmed with RT-PCR.[57] ELISA, IFA, and cell culture may play important roles in confirming current or past infection. Testing can be arranged through a few specialized laboratories, such as the US Centers for Disease Control and Prevention (404-639-1115).

Treatment

The overall clinical management of viral HF is the same as for septic shock.[1–3,58] Patients should be managed in an intensive care unit when possible, with maintenance of strict viral HF infection prevention and control procedures. The possibility of DIC should be assessed and treatment with appropriate blood products implemented. Intravenous access is usually indicated. Because of the risk of bleeding and hematomas at insertion sites and the risk of nosocomial contamination, caution should be exercised in the use of central intravascular catheters, intramuscular and subcutaneous injections, arterial puncture, and procoagulants (e.g., nonsteroidal anti-inflammatory drugs).

Although aggressive oral and intravenous hydration is the mainstay of supportive care, this may pose a challenge in infants and young children requiring constant encouragement and assistance to drink and supervision of intravenous catheters. Hydration by intraosseous or subcutaneous routes has also been employed.[58a]

Isotonic intravenous fluids (i.e., lactated Ringer solution or normal saline) with or without added dextrose are recommended based on the finding of marked hyponatremia in many patients with EVD.[37] Pain and fever should be treated with acetaminophen, tramadol, or narcotics as necessary, and vomiting should be treated with ondansetron. Gastric ulcer prophylaxis with a proton-pump inhibitor or H_2-blocking agent also is recommended.

Broad-spectrum antibacterial or antiparasitic therapy, or both, with specific consideration of antimalarial agents and doxycycline for tickborne rickettsial diseases, should be given until a diagnosis can be confirmed. If fever persists or begins anew after initially resolving, secondary bacterial infection should be suspected.

The massive 2013–2016 outbreak in West Africa prompted accelerated clinical trials and occasional compassionate use of various experimental therapeutic approaches to EVD, including the use of convalescent plasma, monoclonal antibodies, and various antiviral compounds.[59–61] Although early-phase clinical trials have demonstrated the safety of some of these approaches, efficacy has yet to be demonstrated definitively, perhaps in part because studies were started too late and enrolled too few patients to reach target enrollment and statistical endpoints. These products remain experimental and are not generally available.

The antiviral drug ribavirin reduces mortality of Lassa fever. The drug is administered intravenously for 10 days as a loading dose of 30 mg/kg (maximum, 2 g), followed by 15 mg/kg (maximum, 1 g) every 6 hours for 4 days, and then by 7.5 mg/kg (maximum, 500 mg) every 8 hours for another 6 days.[62] Ribavirin should be diluted in 0.9% saline and infused slowly, with the dose diminished in people with a creatinine clearance of less than 50 mL/min. Based on limited data, the drug also appears to be efficacious for the South American HFs.[63,64]

The main side effect of ribavirin is a dose-dependent, mild or moderate hemolytic anemia that infrequently necessitates transfusion and disappears with cessation of drug treatment. Rigors may occur when ribavirin is infused too rapidly.[62] Relative contraindications to use in the pediatric population include severe anemia or hemoglobinopathy, renal insufficiency, decompensated liver disease, and known hypersensitivity. Hemoglobin, hematocrit, and bilirubin levels should be monitored.

Transfusion of appropriately titered convalescent plasma within the first 8 days of illness reduces the mortality rate for Argentine HF.[63] However, this therapy has been associated with a convalescent-phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of those treated. Direct comparison of the efficacy of convalescent plasma and ribavirin for Argentine HF has not been conducted. Animal studies show convalescent plasma to be efficacious for Lassa fever, but only if it contains a high titer of neutralizing antibody (which cannot be assumed uniformly) and there is a close antigenic match between the infecting viruses of the donor and recipient.[65] In most countries, no stockpile of immune serum is available for patients with viral HF.

The treatment of LCMV infection is supportive. Anti-inflammatory drugs such as corticosteroids may be considered for severe CNS disease. The single surviving patient in a cluster of LCMV cases related to transplanted organs received ribavirin and had a reduction of immunosuppressive therapy.[66]

Hospital Discharge and Management of Convalescence

Viremia usually clears rapidly in survivors, although clearance can be delayed for months or even years from a few immunologically protected sites, especially the testes and chambers of the eye.[22,67,68] It has become customary to require a negative RT-PCR test result for blood samples as a criterion for discharge, although experience over the years before this practice was adopted does not suggest virus shedding or any transmission risk after acute symptoms resolve, with the exception of sexual transmission.[18,69,70]

Convalescence from viral HF can be prolonged. A host of short-term and long-term problems have been reported. Persistent arthralgia and myalgia, general weakness and fatigue, headache, and visual problems are among the most prominent, sometimes lasting years after resolution of acute disease.[67,71–78] Post-EVD uveitis is a common problem that can result in significant loss of visual acuity, including complete blindness, if untreated. Sensorineural deafness occurs in up to 30% of patients after Lassa fever and has been reported after Venezuelan HF and EVD.[2,3,79] Although less easily measured, the mental health impacts of viral HF undoubtedly are often profound. Depression, anxiety, and posttraumatic stress disorder are common in these patients, who have survived severe illness with lasting sequelae, often have lost family members to the same disease, and have endured significant stigmatization on recovery.

Survivors of viral HF should be evaluated regularly after discharge by general history and physical and mental health examinations and referred for social services. For survivors of filovirus infection, eye examinations, including slit-lamp examinations to screen for uveitis, should be performed. Clinical management during convalescence usually is supportive. Sulfasalazine has been effective for arthralgia refractory to nonsteroidal anti-inflammatory drugs. Psychological counseling or pharmacotherapy often is warranted.

Prevention

All patients with a syndrome compatible with viral HF should be presumed infectious and kept isolated under standard HF precautions until a specific diagnosis is made. Placement in a negative-airflow room is prudent, but hermetically sealed isolation chambers are not required. Access to the patient should be limited to designated staff and family members with specific training on infection control guidelines and the use of personal protective equipment.

Personal Protection and Nursing Precautions

Specific viral HF isolation precautions (i.e., mask, double gloves, gown, protective apron, face shield, head covering, and shoe covers or rubber boots) are recommended.[80] Positive airway pressure masks and other small-particle aerosol precautions should be used when performing procedures that can generate aerosols, such as endotracheal intubation. Items that were in direct contact with a patient with a viral HF can be decontaminated using chlorine bleach or one of various commercially available lysis buffers.

Contact Tracing

People with unprotected direct contact with a patient during the symptomatic phase of illness should be monitored daily for evidence of disease for 21 days after the last contact. If possible, contacts should check their temperature daily and record the results in a log. Confinement of asymptomatic people is usually not warranted, but those who develop signs or symptoms compatible with a viral HF should be isolated immediately until the diagnosis can be excluded.

Fortunately, the low secondary attack rates of filoviruses and arenaviruses afford a measure of reassurance, even when cases go unrecognized, as long as proper barrier nursing is maintained. Because mild cases, which may be more difficult to recognize, usually have low infectiousness, missed or delayed diagnosis of these patients is unlikely to pose a problem from the standpoint of infection control.

Vaccines

Several experimental vaccine candidates show promise for filoviruses and arenaviruses, including a recombinant vesicular stomatitis virus-based vaccine for EVD that showed 100% efficacy in a phase III trial conducted during the 2013–2016 outbreak in West Africa.[81] The live, attenuated vaccine Candid #1 decreases morbidity and mortality rates for Argentine HF and may protect against Bolivian HF, although it does not appear to cross-protect against other arenaviruses.[82] However, the vaccine is not approved in the United States, and supplies are insufficient even for Argentina, where it is produced.

Postexposure Prophylaxis

Various experimental drugs and vaccines have been used as postexposure prophylaxis on the basis of compassionate use for people potentially exposed to Ebola virus, but the efficacy of these measures can not be determined.[83–85] For arenaviruses, postexposure prophylaxis with oral ribavirin (35 mg/kg loading dose [maximum 2.5 g], followed by 15 mg/kg [maximum 1 g] three times daily for 10 days) may be considered for people with direct unprotected contact with blood or body fluids (e.g., needle stick injury, splash of blood to mucous membranes).[86,87] Prophylaxis should not be given if the only exposure was during the incubation period. Convalescent plasma is efficacious as postexposure prophylaxis for Argentine HF.[63]

Reservoir and Vector Control

Effective and sustainable control measures usually entail avoidance of known reservoir habitats or, when this is not feasible, implementation of measures to prevent direct contact with virus vectors and reservoirs and their excreta.[88] Most successful prevention programs integrate biologic and chemical control measures with education and regulation to change human behaviors that put people at risk. Although it is not possible or even desirable to completely eliminate the various animal reservoirs, trapping rodents may occasionally be useful in outbreaks and more routinely for control of mice and LCMV inside homes.

Key Points

Filovirus and Arenavirus Hemorrhagic Fever

Diagnosis

- The nonspecific clinical manifestations of filovirus and arenavirus hemorrhagic fever (HF) make clinical diagnosis of single cases extremely difficult, especially early in the course of illness.

- Viral HF should be considered in febrile patients with a compatible clinical syndrome and history of travel and exposure, especially if the patient fails to respond to empiric treatment for the usual infectious diseases prevalent in the area.

- Despite the name, hemorrhage is seen in a minority of patients with viral HF, and its absence should not be used to exclude the diagnosis.

Management

- Treatment of viral HF usually is supportive and follows guidelines for the management of septic shock.

- Ribavirin and treatment with convalescent plasma have demonstrated efficacy in a few arenavirus HFs.

Prevention

- All patients with a syndrome compatible with filovirus or arenavirus HF should be presumed infectious and kept isolated under strict HF precautions until a specific diagnosis is made.

RNA Viruses: Retroviridae

OUTLINE

231 Introduction to Retroviridae
232 Human T-Cell Lymphotropic Viruses
233 Human Immunodeficiency Virus

231

Introduction to Retroviridae

Katherine Luzuriaga

The Retroviridae are a large family of enveloped RNA viruses that primarily infect vertebrates.[1] Retroviruses require the generation of a double-stranded DNA genome (i.e., provirus) and integration within host DNA for the production of viral progeny. Integration of proviral DNA can modify the host genome to produce transforming genes, or oncogenes, and research into this process has provided insights into the molecular basis of carcinogenesis. Retroviruses also have medical importance as potential vectors for gene transfer and gene therapy.[2]

Human endogenous retroviruses (HERVs) consist of proviral DNA or partial genomes that have been integrated into host genomes,[3] and they can constitute up to 8% of human genomic DNA. HERV proviral DNA in germline cells can be passed from parents to their offspring. Transcription of HERV elements does not result in the generation of infectious viruses, but it can produce functional proteins, which play a role in normal physiologic processes, including embryonic development. Although implicated in several diseases, the precise role of HERVs as etiologic or contributing agents of disease is unknown.[3,4]

Retroviruses that are passed horizontally through blood, sexual secretions, or breast milk are known as exogenous retroviruses. Human pathogens include human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2), which are associated with T-lymphocyte lymphomas and neurologic disease, and human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2), the causative agents of acquired immunodeficiency syndrome.

Retroviruses are composed of lipid-enveloped particles that are 80 to 100 nm in diameter. They have a protein core that contains two linear, positive-sense, 7- to 11-kb, single-stranded RNA genomes and viral enzymes important for viral replication (i.e., protease, reverse transcriptase, and integrase). Glycoprotein spikes in the lipid membrane envelope determine the host range of retroviruses through their interaction with target cell surface receptors and coreceptors. After virus entry into the cell, linear, double-stranded, proviral DNA is made from the single-stranded RNA of the virus by the viral reverse transcriptase enzyme. Integration of the provirus into the host genome is mediated by the viral enzyme integrase and is necessary for the production of viral particles. The long-term stability of the integrated provirus and its transmission to the cell's progeny provide the basis for persistence of the retrovirus over the lifetime of the host.

Regulatory sequences (i.e., long terminal repeats) on either end of the proviral genome flank the coding regions for viral structural (gag) proteins, envelope (env) proteins, and enzymes (i.e., DNA polymerase [pol], reverse transcriptase, and integrase). Some retroviral genomes (including those of HIV) contain at least two additional genes, *tat* and *rev*, that are essential for virus replication. Retroviral genomes also can contain various accessory genes, which can modify the replication kinetics and pathogenicity of the viruses.

Recombination and errors in reverse transcription in retroviruses can generate genomic diversity. Various selective pressures (e.g., virus cell tropism and growth fitness, host immune responses, antiretroviral therapies) can drive the evolution of a genetically diverse group of viral variants (i.e., quasispecies) over the course of infection. The evolution of the quasispecies provides a mechanism by which retroviruses can evade mechanisms of control such as host immune responses and antiretroviral therapies.

Retroviruses use host cell machinery to synthesize and process viral genomes, messenger RNA, and proteins necessary for the generation of progeny viral particles. Virion assembly requires encapsidation of viral RNA and takes place primarily at the cell plasma membrane. As the virion buds through cellular membranes, it picks up a lipid bilayer along with the viral envelope glycoproteins and several host cell membrane proteins.

Key Points

Retroviridae Characteristics

- Enveloped RNA viruses
- Spikes of glycoprotein in the lipid envelope mediate host cell entry.
- Viral reverse transcriptase converts the single-stranded RNA genome into a double-stranded provirus, and viral integrase mediates integration into the host genome.
- Integration into the host genome is required for production of virus progeny and forms a barrier to cure.
- Errors in reverse transcription and recombination generate genomic diversity Human pathogens include human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) and human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2).

Human T-Cell Lymphotropic Viruses

Katherine Luzuriaga

Epidemiology

Human T-cell lymphotropic (or lymphoma) viruses (HTLVs) are deltaretroviruses. The two most clinically important HTLVs are HTLV type 1 (HTLV-1) and HTLV type 2 (HTLV-2).[1,2] Infections with HTLV-3 and HTLV-4 have been identified in central African populations, but their clinical significance is unclear.[3,4]

HTLV-1 and HTLV-2 are most prevalent in southwestern Japan, the Caribbean, Melanesia, and parts of Africa. Around the world, an estimated 5 to 10 million people are infected with HTLV-1, with disease manifesting in only 5% of cases.[5] In the United States, about 1 in 6250 volunteer blood donors has antibodies to HTLV-1 or HTLV-2. However, foci of HTLV-1 infection have been reported from the Gulf Coast states and from New York City among people who were born in the Caribbean or had sexual contact with people from that area. Endemic foci of HTLV-2 infection exist among the Guayani Indians of Panama and some Native Americans living in Florida and New Mexico. In the United States, Europe, South America, and Asia, HTLV-2 infection is four times more common than infection with HTLV-1 among injection drug users.

Genomic similarities between HTLV and simian T-lymphotropic viruses (STLVs) suggest that the human viruses are derived from viruses transmitted to humans from nonhuman primates. Human populations that are exposed to nonhuman primates through hunting, butchering, or keeping primates as pets appear to be at increased risk for HTLV infections. STLVs do not appear to be transmitted to humans through occupational exposure to nonhuman primates (e.g., employment in primate centers or laboratories). HTLVs are spread by three modes: sexual contact, infusion of blood or blood products, and breastfeeding. Parenteral exposure to HTLV-1–contaminated blood is an efficient route of transmission.

Since 1988, all US blood donors have been screened for HTLV-1 antibodies and excluded if seropositive. HTLV-3 and HTLV-4 appear to be serologically indistinguishable from HTLV-1 and HTLV-2.[4] Because the viruses are infectious only when present in lymphocytes, there is no risk of infection from serum or clotting factors, and people with hemophilia do not have high rates of seropositivity. HTLV-1 and HTLV-2s infection occur in childhood and appear to be associated principally with transmission through breast milk.[6]

Rates of 4% to 22% have been reported for mother-to-child transmission, and most cases are thought to occur through breastfeeding.[7] The risk of transplacental or perinatal transmission of viruses from an infected mother is about 5% for an infant who is not breastfed, whereas the risk of infection is about 25% for the breastfed child. Infected women should not breastfeed their infants.

HTLV-1 is not transmitted by casual contact. Medical workers are not at risk of contracting infection if they observe universal precautions.

Clinical Manifestations

HTLV-1

Infection with HTLV-1 can cause two diseases: adult T-cell leukemia/lymphoma (ATLL) and HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP).[8] The cumulative lifetime risk of developing either disease is approximately 5% for infected people.[5]

ATLL is a clonal malignancy of well-differentiated CD4$^+$ T lymphocytes, occurring in about 2% to 4% of HTLV-1–infected people.[9] Although CD4$^+$ and CD8$^+$ T lymphocytes are infected, the leukemic cells are exclusively CD4$^+$.[10,11] The HTLV-1 DNA provirus is integrated into the genome of malignant cells. Infection appears to have a long latency period, usually manifesting clinically in persons 40 to 60 years of age after many years of asymptomatic infection. The disease typically is aggressive and rapidly fatal. It is associated with hypercalcemia and characteristic lytic lesions of bone, ascribed to the ability of virus-encoded *trans*-activating factor tax to activate genes for parathyroid hormone production.

HAM/TSP is a slowly progressive neurologic disease associated with permanent weakness in the legs, paresthesias, long tract neurologic abnormalities, and urinary incontinence.[12] Although these manifestations of infection are evident in less than 1% of all people infected with HTLV-1, they occur in about 20% of those infected by contaminated blood. Antibodies to HTLV-1 are found in the cerebrospinal fluid of patients with this disorder. Treatment with corticosteroid or other immunosuppressive agents is only modestly beneficial. HAM/TSP affects patients of all ethnic groups, but it is most prevalent in geographic regions where HTLV-1 has been endemic for a long time.[13]

HTLV-1 has been associated with isolated cases of uveitis, arthritis, polymyositis, and panbronchiolitis. HTLV-1–infected people commonly come to medical attention with skin lesions. Skin manifestations are observed in 43% to 72% of ATLL cases.[14] Children can manifest infective dermatitis associated with HTLV-1 (IDH), a severe form of chronic eczema associated with *Streptococcus pyogenes* and *Staphylococcus aureus* infections.[15]

HTLV-2

HTLV-2 appears to have originated in Africa several thousand years ago.[16] DNA provirus has been detected in breast milk, and maternal-child transmission, probably due to breastfeeding, is documented. Rare cases of mycosis fungoides and large granular lymphocytic leukemia have been detected in HTLV-2–infected individuals, but causality has not been proved. HTLV-2 does appear to be associated with an HAM/TSP-like neurodegenerative disease and other neurologic disorders.[17] Bacterial skin infections have been described in those coinfected with HTLV-2 and HIV-1.

Key Points

Characteristics of Human T-Cell Lymphotropic Viruses

Epidemiology

- Human T-cell lymphotropic virus types 1 and 2 (HTLV-1, HTLV-2) are most clinically important.
- Between 5 and 10 million people are infected worldwide.
- HTLV-1 and HTLV-2 are most prevalent in southwestern Japan, the Caribbean, Melanesia, and parts of Africa.
- HTLVs are spread by sexual contact, infusion of blood or blood products, and breastfeeding.
- Most mother-to-child transmission occurs through breastfeeding, and avoidance of breastfeeding limits new infections.

Clinical Manifestations

- Adult T-cell leukemia/lymphoma (ATLL) is a clonal malignancy of well-differentiated CD4$^+$ T lymphocytes, and it occurs in about 2% to 4% of HTLV-1–infected people.
- HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP) is a slowly progressive neurologic disease.
- HTLV-1 infection can manifest with dermatitis, uveitis, arthritis, polymyositis, and panbronchiolitis.

233

Human Immunodeficiency Virus

Katherine Luzuriaga

Human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2) are members of the *Lentivirus* genus of the Retroviridae family.[1] HIV-1 and HIV-2 appear to have entered humans as a result of cross-species transmission of simian immunodeficiency viruses (SIVs). HIV-1 is similar to an SIV that infects chimpanzees (SIV_{cpz}; Table 233.1), and HIV-2 is similar to SIV strains that infect sooty mangabeys (SIV_{sm}). The simian viruses do not cause disease in their natural hosts. Comparative genomic analyses of SIV_{cpz} and HIV-1 have documented at least 3 independent transmissions of SIV_{cpz} strains to humans. The current HIV-1 pandemic likely resulted from 1 of these transmission events in the first half of the 20th century.[2,3] Similar analyses also suggest that HIV-2 resulted from the transmission of SIV_{sm} to humans in West Africa in the first half of the 20th century.[4]

TABLE 233.1

Comparison of Human Immunodeficiency Viruses Types 1 and 2

	HIV-1	HIV-2

Source virus	Chimpanzee simian immunodeficiency virus	Sooty mangabey simian immunodeficiency virus
Geographic distribution	Worldwide	West Africa; India
Transmission	Sexual; contaminated needles; blood transfusion; mother-to-child	Sexual; mother-to-child; blood transfusion; lower overall transmissibility than that of HIV-1
Mother-to-child transmission	25%–35%[a]	≤4%[a]
Clinical manifestations	Lymphadenopathy; wasting syndrome; central nervous system disease; $CD4^+$ lymphocyte depletion and immunodeficiency	Same as those of HIV-1 but generally less rapid disease progression

[a] Transmission rates without antiretroviral therapy.

Human Immunodeficiency Virus Type 1

Life Cycle

The mature HIV-1 virion is approximately 110 nm in diameter and is composed of a core surrounded by a lipid bilayer envelope. The virion core consists of a structural shell composed of a protein (p24) processed from the gag precursor polypeptide. Within this shell are 2 copies of single-stranded RNA, 2 transfer RNA primers of host cell origin, and multiple copies each of the virus-encoded reverse transcriptase, integrase, and RNAse H enzymes. Matrix protein (p17), another product of the gag polypeptide precursor, surrounds the virion core and is associated with the transmembrane glycoprotein of the viral envelope (gp41). At least 3 more virus-encoded proteins (vpr, vif, and nef) are packaged within the virion. These proteins are active early in the intracellular life cycle of HIV-1 and contribute to the efficiency of infection. Trimers of an external glycoprotein (gp120), anchored by gp41, protrude from the lipid bilayer envelope. The gp120 glycoproteins contain binding sites for the cell surface HIV-1 receptor (CD4 molecule) and coreceptors (chemokine receptors) and therefore are functionally important in virus attachment and entry.

Virus–cell membrane fusion begins with the interaction of gp120 with the first immunoglobulin-like domain of the $CD4^+$ molecule expressed on the cell surface. This interaction causes conformational changes in gp120 that allow binding of gp120 to the coreceptor. Binding results in exposure of a hydrophobic domain in gp41 that in turn leads to the insertion of this domain into the cell membrane and the initiation of viral envelope–cell membrane fusion.

The 9-kb HIV-1 genome is similar in organization to that of other retroviruses, but it has at least 6 other genes (*tat, rev, vpr, vpu, vif,* and *nef*) that are not found in nonprimate retroviruses. Each of these genes encodes a protein that has been implicated in virus replication and pathogenicity.[5]

After internalization and uncoating of the viral core, a new viral life cycle begins with the generation of a DNA transcript of viral RNA through the activity of the viral reverse transcriptase. As the linear, double-stranded DNA provirus is generated, it remains associated with RNA, matrix proteins, and the viral integrase enzyme as a preintegration complex. For completion of the viral replication cycle, the preintegration complex must be transported from the cytoplasm to the nucleus and integrated into host genomic DNA. The extent to which integration and subsequent virion synthesis occur appears to depend on the cell cycle stage and activation state of the infected cell.[6] Cells with integrated provirus represent long-lived reservoirs for viral persistence and barriers to eradication of the virus from infected people.

Virion assembly takes place primarily at the cell plasma membrane. Structural (*gag*, envelope) and viral enzyme genes encode precursor proteins that are processed and cleaved to produce multiple gene products. Cleavage of the gag structural proteins by the viral protease enzyme occurs during viral assembly and is essential for the proper assembly of infectious virions. As the virus buds through cellular membranes, it acquires a lipid bilayer along with viral envelope glycoproteins. Understanding of the viral life cycle has contributed to the development of antiretroviral agents that block viral entry or inhibit viral enzymes, including reverse transcriptase, protease, and integrase.

Early Infection Events

The CD4 molecule is the primary cellular receptor for HIV-1; cells that express this molecule on their cell surfaces ($CD4^+$ T lymphocytes and cells of monocyte or macrophage lineage) are major targets for HIV-1 infection. Members of the chemokine receptor family are coreceptors for HIV.[7] Cell surface chemokine receptors are 7-transmembrane, G-protein–coupled receptors that transduce chemokine binding into intracellular signals, which in turn lead to the activation and migration of leukocytes. The configuration of cysteine motifs in chemokines is the basis for structural groupings (C-C-C or CC-chemokines; C-X-C or CXC-chemokines) that determine differences in biologic activities. Most HIV-1 strains use the CCR5 or CXCR4 (also known as LESTR or fusin) coreceptors.

CCR5 appears to be important especially in the initial establishment of infection. HIV-1 infection is uncommon in people with a homozygous 32-bp deletion in CCR5; their lymphocytes do not express this chemokine receptor on cell surfaces and are relatively resistant to infection with primary HIV-1 isolates in vitro. Nonetheless, several HIV-1–infected people who are homozygous for this defect have been identified, a finding suggesting that under some circumstances, other coreceptors could be used in the establishment of infection. Although heterozygosity for the CCR5 deletion mutant does not appear to protect from the acquisition of infection, studies in both adults and children indicate that it may protect against disease progression.

Following virus entry, HIV-1 proteins can interact with multiple cellular proteins to enhance virus replication.[8] For example, HIV-1 Tat interacts with the cellular protein cyclin-T1 to increase the efficiency of proviral transcription; the interaction of HIV-1 Gag with tumor suppressor gene 101 (TSG-101) enhances virus budding from the plasma membrane. Several cellular proteins that restrict the replication of primate lentiviruses also have been identified. CEM-15 is a member of the APOBEC 3 family of proteins. These proteins are cytidine deaminases that are packaged into retroviruses; during reverse transcription, they introduce G to A hypermutations that alter the integrity of the proviral DNA. HIV-1 Vif restores HIV-1 infectivity by complexing with CEM-15 and targeting it for proteosomal degradation, thus preventing its incorporation into virions. TRIM-5α is a cellular restriction factor that appears to interfere with uncoating of the viral RNA following entry.

Mother-to-Child HIV Transmission

Mother-to-child HIV-1 transmission can occur during gestation (in utero), during delivery (intrapartum), or in the postpartum period through breastfeeding. Although admixture of maternal-fetal blood is a potential mechanism for in utero and intrapartum transmission, most infections are thought to occur on mucosal (ocular or gastrointestinal) exposure to maternal blood and cervicovaginal fluids during delivery or to breastmilk after birth. CD4$^+$ T lymphocytes are the likely major source of virus production and dissemination throughout the body. Regardless of the route of infection, the gastrointestinal tract appears to be a major site of viral replication, persistence, and CD4$^+$ T-lymphocyte depletion throughout infection.[9,10]

Early Infant Diagnosis and Therapy

HIV-1 DNA can be detected by means of polymerase chain reaction assay in peripheral blood mononuclear cells of infected infants at birth, a finding suggesting in utero infection. In infants who are not breastfed, results of polymerase chain reaction assay are negative in the majority of infected infants (≤75%) at birth, but they become positive at 2 to 4 weeks of age; this finding suggests intrapartum transmission of HIV-1. In breastfeeding cohorts, up to 40% of infants can acquire HIV-1 through breast milk transmission. The administration of antiretroviral therapies can markedly reduce the risk of mother-to-child HIV-1 transmission.[11]

Rapid increases in the plasma HIV-1 RNA copy number to 10^5 to 10^7 copies/mL have been documented in vertically infected infants during the first weeks of life. By contrast, plasma HIV-1 RNA levels gradually decrease in untreated infants after the first 1 to 2 years of life, but mean plasma HIV-1 RNA levels do not drop to less than 10^5 copies/mL until at least the third year of life. A continued reduction in plasma HIV-1 RNA (mean −0.2 to −0.3 log decline per year) has been observed in vertically infected children through 5 to 6 years of age. Plasma HIV-1 RNA levels during infancy do not appear to distinguish between infants with rapid and slow disease progression. However, after 3 to 4 years of age, plasma HIV-1 RNA levels are predictive of disease progression. Reductions in plasma HIV-1 RNA after antiretroviral therapy have been associated with clinical benefit. The initiation of antiretroviral therapy in early infancy can preserve immune function and reduce HIV-associated morbidity and mortality rates[12–14]; early diagnosis and treatment of infants are recommended routinely, irrespective of symptoms or CD4 counts.[15,16] Initiation of combination antiretroviral therapy within hours of birth can markedly limit the generation of a persistent HIV reservoir.[17]

Human Immunodeficiency Virus Type 2

HIV-2 was first isolated in the mid-1980s from people with acquired immunodeficiency syndrome (AIDS) in West Africa. Since then, most cases of HIV-2 infection have been reported from West Africa, although cases have also been reported from Zimbabwe and India.[18] The distribution of HIV-2 infections in West Africa coincides with the natural habitat of the sooty mangabey. HIV-2 is thought to be a zoonosis resulting from cross-species transmission of SIV_{sm}. HIV-2 and SIV_{sm} are genomically similar and share an accessory gene, *vpx,* not found in other primate lentiviruses.

To a lesser extent, HIV-2 also shares structural and genomic similarities with HIV-1. The HIV-2 *gag* and *pol* genes share approximately 60% homology with corresponding HIV-1 genes, whereas the *env* genes share only 30% to 40% homology. Viral genomic differences form the basis for molecular assays that distinguish between HIV-1 and HIV-2. Corresponding differences in viral proteins form the basis for antibody tests that distinguish between infections with these viruses.

Heterosexual and mother-to-child transmission of HIV-2 has been documented. Transmission through blood transfusion also occurs. Transmission through contaminated needles is postulated but not well documented. Heterosexual and mother-to-child transmissions of HIV-2 appear to occur less readily than transmission of HIV-1. Antiretroviral therapy can reduce the risk of mother-to-child transmission of HIV-2.

The clinical manifestations of HIV-2 infection are similar to those of HIV-1. Lymphadenopathy, wasting syndrome, central nervous system disease, and $CD4^+$ depletion are common findings.

Opportunistic infections and malignant diseases are common complications. The rate of CD4$^+$ depletion is much slower, and the median time from infection to the development of AIDS is longer after HIV-2 infection than after HIV-1 infection. HIV-1 and HIV-2 coinfection occurs and follows a clinical course similar to that in people infected with HIV-1 alone.

The cause of the reduced transmissibility and pathogenicity of HIV-2 is unclear. Peripheral blood proviral load in HIV-2 infection is similar to that in HIV-1 infection, but plasma RNA levels are much lower in HIV-2–infected people than in HIV-1–infected people. Improvements in molecular techniques to detect, quantify, and characterize HIV-2 should allow improved understanding of the pathogenesis of HIV-2 infections in humans.

Key Points

Human Immunodeficiency Virus

Human Immunodeficiency Virus Type 1

Life Cycle

- 9-kb genome encodes 3 structural and 6 regulatory genes.
- Viral integrase mediates production of double-stranded DNA; integration of this provirus into the host genome is required for completion of the virus life cycle and serves as a barrier to cure.
- Understanding of the virus life cycle has led to the development of antiretroviral agents that block viral entry or inhibit viral enzymes.

Early Infection Events

- Viral entry is mediated by interaction between viral surface glycoproteins and host cell surface molecules (CD4, chemokine receptors).
- Multiple host proteins can interact with viral proteins to enhance or inhibit viral replication.

Mother-to-Child Transmission

- Mother-to-child transmission can occur during gestation (in utero) or, more commonly, during delivery (intrapartum) or in the postpartum period through breastfeeding.

- Antiretroviral regimens effectively prevent this transmission.

Early Infant Diagnosis and Therapy

- Early infant diagnosis requires direct detection of the virus in peripheral blood samples.

- Early diagnosis and antiretroviral therapy are routinely recommended to reduce HIV-related morbidity and mortality.

- Very early therapy (within hours of birth) can restrict the size of long-lived HIV reservoirs.

Human Immunodeficiency Virus Type 2

- HIV-2 is transmitted through sexual contact and from mother to child but appears to be less readily transmitted than HIV-1.

- HIV-2 infection is associated with immunodeficiency, but the rate of $CD4^+$ depletion is slower and the median time from infection to the development of AIDS is longer than with HIV-1.

236 Enteroviruses and Parechoviruses
237 Hepatitis A Virus
238 Rhinoviruses

234

Introduction to Picornaviridae

Kevin Messacar, John F. Modlin, Mark J. Abzug

The family Picornaviridae represents a large group of small, positive-stranded RNA viruses that infect a wide variety of hosts throughout the animal kingdom and are now classified by RNA sequence alignment (Table 234.1).[1] Included in the Picornaviridae family are 3 genera commonly associated with human infection: *Enterovirus, Parechovirus,* and *Hepatovirus*.

TABLE 234.1
Classification of the Human Picornaviruses

Genus	Species
Enterovirus	*Human enterovirus A*
	Human enterovirus B
	Human enterovirus C
	Human enterovirus D
	Human rhinovirus A
	Human rhinovirus B
	Human rhinovirus C
Parechovirus	*Human parechovirus*
Hepatovirus	*Hepatitis A virus*

Seven enterovirus species (*human enterovirus A* through *D* and *human rhinovirus A* through *C*), the human *parechovirus* species, and *hepatitis A virus*, the only member of the *Hepatovirus* genus (see Chapter 237), cause human infection. The enteroviruses, rhinoviruses, and parechoviruses each contain multiple serotypes, which are differentiated from one another both by RNA sequence and by neutralization with immune serum. Important clinical and epidemiologic characteristics are associated with viral serotype, and some biologic and genetic diversity also exists within each serotype.

Enteroviruses, rhinoviruses, and hepatitis A virus can be distinguished from one another on the basis of certain biophysical, clinical, and epidemiologic properties. Rhinoviruses replicate optimally at 33°C, thus reflecting their adaptation to the nasal mucosa. They are unstable at a pH <6 and can be recovered only from the respiratory tract. *Enterovirus D68* is unique among enteroviruses and shares similar optimal growth temperature and acid lability with rhinoviruses. Other enteroviruses and hepatitis A virus, which remain stable over a wide pH range, survive the acid environment of the stomach and are shed in the feces. Enteroviruses replicate in diverse tissues and cause many different diseases. Hepatitis A virus replication is limited to liver cells, and extrahepatic clinical manifestations of hepatitis A infection are rare. The physical, clinical, and epidemiologic properties of the parechoviruses are indistinguishable from those of the enteroviruses.

Biology

The major physical characteristics of picornaviruses are shown in Box 234.1. Picornavirus infection at the cellular level requires the presence of specific host cell membrane proteins that serve as receptors for viral attachment.[2] The receptors for many of the human picornaviruses have been identified and characterized.

Box 234.1

Major Physical Characteristics of the Picornaviridae

Size: 24–30 nm

Symmetry: icosahedral

Envelope: none

Genome: single-stranded RNA, $2.3–2.8 \times 10^6$ daltons (7.5 kb)

Penetration, uncoating, and release of the positive-stranded RNA genome into the cytoplasm occurs within minutes at 37°C. The RNA functions as a monocistronic messenger, the product of which is a large polyprotein that is cleaved in a series of steps into both structural and nonstructural regulatory proteins. Four capsid proteins (VP1, VP2, VP3, and VP4) are assembled in equimolar amounts into the capsid. Progeny RNA are copied from the genome by a negative-stranded RNA intermediary and are encapsidated to complete the replication cycle. In vitro infection produces approximately 10^4 to 10^5 particles/cell, but the number of infectious particles is 10- to 1000-fold lower. Host protein and RNA synthesis is compromised within 3 hours of cell infection, and cell lysis occurs within 8 hours, with release of the progeny virions.

Picornaviruses are resistant to ether, chloroform, and alcohol but are inactivated by formaldehyde, phenol, and irradiation. They are rapidly inactivated at temperatures in excess of 50°C.

Polioviruses

Stephanie B. Troy, Yvonne A. Maldonado

Pathogen and Pathophysiology

Polioviruses are positive-stranded RNA viruses belonging to the Picornaviridae family. They have a naked protein capsid consisting of 4 structural proteins, VP1 to VP4. The genomic RNA is approximately 7440 to 7500 nucleotides in length. For genome replication, RNA-dependent RNA polymerase is encoded that lacks a proofreading mechanism. Consequently, poliovirus can mutate rapidly with replication. The 3 serotypes of poliovirus are antigenically distinct, but all 3 have 70% nucleotide identity.[1] Polioviruses can be stored indefinitely at −20°C, but they are inactivated by formaldehyde, chlorination, and ultraviolet light.

Humans are the only known natural hosts; however, poliovirus can replicate in other primates. The virus is propagated exclusively in cultured cells of primate origin because other cell lines lack a functional receptor molecule. Since identification and molecular cloning of the viral receptor, transgenic mice have been developed that are susceptible to all 3 serotypes of poliovirus.[2]

Poliovirus is transmitted primarily by the fecal-oral route and replicates in the pharynx and lower intestinal tract (Table 235.1). Only small amounts of infectious virus are needed to cause infection. Virus is typically shed in the pharynx for 1 to 3 weeks and in the gut for 4 to 8 weeks after primary infection. During reinfection, pharyngeal shedding is rare and fecal shedding is reduced to <3 weeks. The incubation period generally is 7 to 14 days but can be as short as 3 days and as long as 35 days. The virus spreads quickly from the alimentary tract to regional lymph nodes. After several days, minor viremia ensues, and certain sites (e.g., muscle, fat, liver, spleen, and bone marrow) become infected. If virus is contained at this point, subclinical infection occurs. Further replication of virus in these tissues leads to major viremia and the onset of clinical symptoms. The central nervous system is seeded in approximately 1% of infections. The virus also can infect the central nervous system through axonal transport from skeletal muscle[3]; such infection may correlate with the intense myalgia seen at the onset of paralysis in affected patients.

TABLE 235.1

Pathogenesis of Poliovirus Infection

Site of Virus Replication	Days After Acquisition	Clinical Illness
Pharynx and intestine	0–1	Asymptomatic
Regional lymph nodes	1–3	Asymptomatic
Blood (minor viremia), muscle, fat, liver, spleen, bone marrow	3–7	Minor illness
Blood (major viremia), central nervous system	7–21	Major illness

Poliovirus replicates within neurons; the anterior horn cells of the spinal cord are involved most often. Neurons in nuclei of the medulla, vermis of the cerebellum, midbrain, thalamus and hypothalamus, palladium, and motor cortex of the cerebrum also can be involved. Rarely, the posterior horn cells and dorsal root ganglia are infected. Although poliovirus infection usually destroys neurons, injury occasionally is reversible.

Serum neutralizing antibodies develop after approximately 1 week and protect against paralysis but not against reinfection. Immunity to poliovirus infection is serotype specific, without any cross-protection. Immunity persists for life. Local antibody appears 1 to 3 weeks after infection and limits virus replication at the mucosal level. Reinfection occurs; however, the duration of viral shedding is reduced, and viremia does not occur.

Epidemiology

Poliovirus infection occurs primarily in summer and fall in temperate climates and year round in tropical areas. Warm weather favors the spread of virus. Before the Industrial Revolution, poliomyelitis occurred predominantly in an endemic form, infecting most infants early in life. Most infections with poliovirus were inapparent; paralytic disease developed in a small proportion of infected people.

As hygiene and sanitation improved, especially in the more temperate countries, epidemics appeared. Change occurred because of lack of contact with the virus by the youngest populations, and large groups of older children and adults became susceptible. The first large epidemic of paralytic poliomyelitis in the United States occurred in Vermont in 1894 and involved approximately 130 people. Epidemics increased in size and frequency and peaked in 1952, when 57,879 cases were reported in the US. Introduction of the inactivated vaccine in 1955 led to a sharp decline in the number of cases.

In 1988, the World Health Assembly developed the goal of global eradication of poliomyelitis by the year 2000.[4] This objective was determined to be feasible because poliovirus has no animal reservoir, does not survive for long periods in the environment, and induces lifelong immunity after disease or vaccination. Global eradication strategies were developed and implemented, and although poliomyelitis has not been eradicated globally, remarkable progress has been made. Annual cases have dropped more than 99%, from 350,000 in 1988 to 416 in 2013.[5] Wild poliovirus serotype 2 was eradicated globally in 1999, and no wild poliovirus serotype 3 has been isolated since November 2012. Only 3 countries (Afghanistan, Nigeria, and Pakistan) continue to have uninterrupted wild poliovirus transmission. Unfortunately, wild poliovirus has been exported from endemic countries and has caused several large outbreaks in previously poliovirus-free countries, including Tajikistan and the Republic of Congo in 2010, Chad in 2011, and Somalia in 2013 (Fig. 235.1).[6] These outbreaks demonstrate that sustaining high levels of immunization coverage, even in poliovirus-free countries, is critical to eradication efforts.

FIGURE 235.1 **Global wild poliovirus distribution and international spread, 2011 to 2014.** (From World Health Organization; provided by Dr. Stephen Cochi.)

One complicating factor in global eradication is that oral poliovirus vaccine (OPV) can mutate and cause poliomyelitis. OPV can cause vaccine-associated paralytic poliomyelitis (VAPP) in vaccinees or their close contacts, at a rate of approximately 4.7 cases per million births.[7] Congenital humoral immunodeficiencies confer a 3000-fold higher risk of VAPP.[8] Of more concern was the discovery in 2000 that with prolonged replication, OPV can mutate to form vaccine-derived polioviruses (VDPVs), capable of causing poliomyelitis outbreaks.[9] VDPVs are defined as isolates with >1% VP1 sequence divergence from their parental OPV strain for serotypes 1 and 3 and >0.6% sequence divergence for serotype 2.[8] They can evolve from person-to-person OPV spread in undervaccinated communities (circulating VDPVs [cVDPVs]) or from prolonged (>1 year) intestinal OPV replication in patients with congenital humoral immunodeficiencies (immunodeficiency-associated VDPVs [iVDPVs]). Between 2000 and 2014, cVDPV outbreaks occurred in 22 countries and caused >750 cases of paralytic poliomyelitis (Fig. 235.2). The attack rates and severity of disease associated with cVDPV are similar to those seen with wild poliovirus.[10] OPV serotype 2 appears to circulate longer and be transmitted more readily in the community; this feature may explain why serotype 2 accounts for >85% of isolated cVDPVs.[11] The mortality rate was >60% in the >70 patients identified who were excreting iVDPV, but likely because most of the cases were in high- and middle-income countries with good sanitation and high levels of population immunity, iVDPV has not been known to cause an outbreak.[8,12]

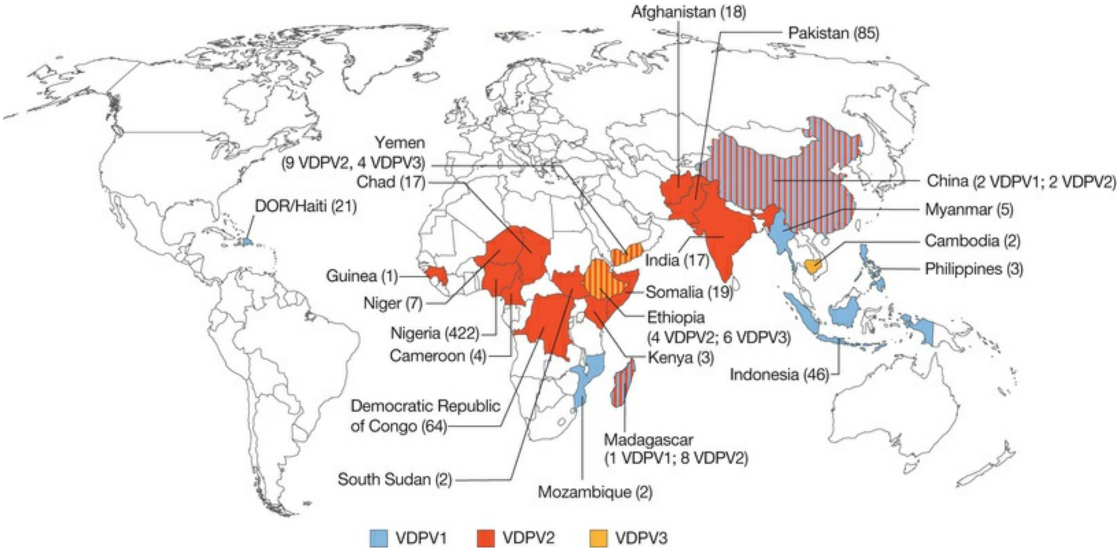

FIGURE 235.2 **Cases of paralytic poliomyelitis from circulating vaccine-derived poliovirus (VDPV), 2000 to 2014.** (Data from www.polioeradication.org.)

Clinical Manifestations

From 90% to 95% of poliovirus infections produce no symptoms or nonspecific minimal symptoms, such as fever, malaise, anorexia, and sore throat. Aseptic meningitis develops in 4% to 8% of infected children, but recovery usually is complete in 5 to 10 days; <1% of infections lead to paralytic disease. Known provocative events for developing paralytic disease include strenuous exercise during the first few days of major viremia and intramuscular injection 2 to 4 weeks before infection.[13,14]

Paralytic illness in children often is biphasic, with an initial self-resolving, minor illness. The child then experiences high fever and intense muscle pain accompanied by a decrease or loss of reflexes. The appearance of paralysis is sudden and progresses to complete loss of motor function in 1 or more extremities over a period of several hours. Maximal loss of function develops within 5 days of onset. The hallmark of poliomyelitis is spotty, asymmetric paresis or paralysis, with larger muscles involved more frequently than smaller muscles (e.g., of the hands and feet) and lower limbs more often affected than upper limbs. Bladder paralysis and bowel atony commonly occur but improve over a period of 1 to 3 days. Pain, spasticity, nuchal and spinal rigidity, and hypertonia occur early and result from lesions in the brainstem, spinal ganglia, and posterior columns. In general, paralysis tends to subside over time, with maximal improvement by 6 months. However, 60% of affected people exhibit some degree of residual deficit. Sensory abnormalities are rare except in patients with the most severe cases.

Bulbar (brainstem) poliomyelitis occurs in 5% to 35% of patients with paralytic cases, is the most severe form of the disease, and can result in respiratory compromise secondary to involvement of the respiratory center in the brainstem or infection of the 9th, 10th, and 12th cranial nerves. Cranial nerve involvement results in paralysis of the pharynx, soft palate, and vocal cords, with subsequent respiratory compromise. Currently, <7% of patients with spinal poliomyelitis die, usually as a result of respiratory failure from paralysis of the respiratory muscles. In contrast, as many as 60% of patients with bulbar paralysis died before modern methods of assisted ventilation became available.

Other diseases can mimic poliomyelitis. Nonpoliomyelitis enteroviruses, especially coxsackievirus A7, enterovirus 71, and more recently enterovirus 68 (by association), can cause sporadic cases, as well as small outbreaks of paralytic disease. Guillain-Barré syndrome causes ascending symmetric paralysis, and infant botulism causes descending symmetric paralysis. West Nile encephalitis can cause unilateral flaccid paralysis, and Lyme disease can cause neuropathy. Acute flaccid paralysis not caused by poliovirus generally occurs at a rate of 2 to 6 cases per 100,000 children <15 years old.[5]

Diagnosis

Results of routine laboratory studies are not distinctively abnormal. The complete blood cell count and differential cell count usually are unremarkable. Examination of cerebrospinal fluid demonstrates changes consistent with aseptic meningitis. Definitive diagnosis can be made when poliovirus is isolated from a clinical specimen in a patient with a compatible clinical syndrome. Poliovirus can be recovered readily from the throat and stool and rarely from the cerebrospinal fluid of infected people. The virus produces cytopathic effects in monolayers of monkey kidney cells, genetically engineered mouse cells with a poliovirus receptor, and human cells within 1 to 2 weeks. VDPVs and wild-type polioviruses, as well as other enteroviruses, cannot be distinguished without additional specific studies such as polymerase chain reaction or antiserum-based microneutralization assays. In the absence of virus isolation, a serologic diagnosis can be made by demonstrating an increase in poliovirus neutralizing antibodies against a specific serotype in paired acute and convalescent serum.

Treatment

Supportive care is the mainstay of treatment. Analgesics and bed rest are indicated. Manual decompression of the bladder, medication to relieve severe muscle spasms, intermittent catheterization, or the shortterm use of a parasympathetic stimulant can be necessary if bladder paralysis exists. Ventilator support can be necessary for patients with respiratory compromise. Although no approved antiviral treatments are currently available, several poliovirus antiviral compounds and antipoliovirus monoclonal antibodies are in clinical or preclinical testing.[15]

Special Considerations

Pregnant women have an increased risk of paralytic disease. Rarely, poliovirus causes an intrauterine infection resulting in abortion or premature delivery; malformations are not a consequence. Infection acquired from a mother incubating the virus at the time of delivery can result in paralytic disease in the newborn. Immunocompromised patients are prone to the development of progressive, often fatal disease. People with B-lymphocyte immunodeficiency are susceptible to chronic or disseminated infection from wild and attenuated vaccine virus.

New neurologic symptoms develop in approximately 25% to 35%

of patients with paralytic disease 25 to 35 years after infection.[16] This "postpolio syndrome" is characterized by muscle weakness, pain, atrophy, and fatigue. The muscles involved are the same as those involved in the original illness. The causes of these changes remain unclear; postulates include neuronal "fallout," slow infection, or immunopathologic mechanisms.

Prevention

Use and Efficacy of Salk and Sabin Vaccines

Poliomyelitis reached pandemic proportions in the US in the first half of the 20th century. During the early 1950s, paralytic disease developed in 10,000 to 20,000 people annually during the summer and fall. Considering that paralytic illness represented <1% of total infections, millions of infected people likely contributed to the spread of virus throughout communities.

The first inactivated poliovirus vaccine (IPV, Salk) was introduced in 1955, just 6 years after the virus had been successfully propagated in tissue culture of nonneurogenic origin.[17] Use of IPV was followed by an immediate decline in paralytic poliomyelitis from 37 to 0.8 cases per 100,000 population in 1961.[18] In 1961 to 1962, live OPV (Sabin) was introduced and quickly supplanted the use of IPV because it was easier to administer, induced lifelong immunity, provided mucosal immunity, and secondarily immunized contacts through fecal shedding of virus.

The initial use of OPV in the US and elsewhere resulted in a dramatic reduction in the global incidence of poliomyelitis. In most developing nations, OPV is still used for routine and mass immunization programs and has resulted in a dramatic decline in paralytic disease in these regions. However, outbreaks of poliomyelitis occurred in developing countries with relatively high rates of vaccine coverage because of suboptimal seroconversion rates, especially in tropical regions. Possible explanations include vaccine instability, vaccine formulation, concurrent enteric infections, malnutrition, and the presence of inhibitory substances in the intestine.[19,20]

To improve immunogenicity, the formulations of both IPV and

OPV were changed in 1987 and 1990, respectively. The newer, enhanced-potency IPV (eIPV) contains 40, 8, and 32 D-antigen units per dose of poliovirus types 1, 2, and 3, respectively, compared with 20, 2, and 4 D-antigen units per dose in the original Salk vaccine. In 1984, Finland experienced a unique epidemic that involved 9 cases of paralytic disease caused by serotype 3 virus. Investigation demonstrated an unexpectedly low rate of seropositivity (i.e., 60%) to type 3 poliovirus in the population. The decline in the seropositivity rate from earlier years was attributed to a decline in serotype 3 poliovirus content of vaccine and a slight change in the immunologic and molecular characteristics of the epidemic virus compared with the vaccine virus.[21] The increased antigenic content of eIPV is associated with a higher seroconversion rate after the administration of fewer doses.[22] Similarly, the newer formulation of OPV contains higher antigen content (10^6, 10^5, and 6×10^5 median tissue culture infective dose [$TCID_{50}$] of Sabin types 1 to 3, respectively, versus 10^6, 10^5, and 3×10^5 $TCID_{50}$ of Sabin types 1–3).[20] The OPV formulation change was made to increase seroconversion to serotype 3, which has historically had lower seroconversion rates than the other 2 serotypes. Both eIPV and OPV produce high serum neutralizing antibody titers after 3 doses, and poliovirus immunity lasts for decades after vaccination.[23–25]

Vaccine-Associated Paralytic Poliomyelitis

After the dramatic reduction in cases of poliomyelitis in the US, concern about VAPP increased. From 1980 through 1995, 132 cases of VAPP were reported in the US.[26] Of these cases, approximately 40% occurred in previously healthy vaccine recipients, 31% in healthy contacts of vaccine recipients, and 24% in immunodeficient people. Serotype 3 is most commonly isolated from patients with VAPP, followed by serotype 2.[7] Seventy-four percent of VAPP cases in OPV recipients occur following the first dose of OPV, and 52% of VAPP cases in contacts of OPV recipients occur in people who have never been vaccinated with OPV. Intramuscular injections within 30 days of immunization with OPV are associated with higher rates of VAPP.[27] The incidence of VAPP in the US remained steady at approximately 4 cases annually over a decade without wild-type paralytic poliovirus infection until the transition to the exclusive use of IPV in the US in 2000.

Alternative Vaccination Strategies

A combined schedule of eIPV and OPV has been used by several countries and has several advantages. First, most VAPP cases could be avoided using a schedule of eIPV followed by OPV because VAPP generally occurs in OPV recipients who have not been vaccinated previously. In addition, several studies have demonstrated that sequential dosing of both eIPV and OPV in either order provides better systemic and mucosal immunity than does administration of either vaccine alone.[23,28–30]

Monovalent OPV (mOPV) against serotype 1 or 3, and bivalent OPV (bOPV) against both serotypes 1 and 3, has been introduced for use in mass immunization campaigns in countries where wild poliovirus is endemic or has been imported. Immunization with mOPV leads to approximately 3 times more type-specific antibody concentrations than trivalent OPV.[10,31,32] However, mOPV1 and mOPV3 use in place of the trivalent vaccine may have contributed to an outbreak of circulating VDPV type 2 in Nigeria because fewer children were immune to serotype 2.[10]

Efforts have been made to make eIPV more affordable for developing countries. eIPV has been combined with other injectable vaccines into pentavalent and even hexavalent vaccines without decreasing immunogenicity.[33] Another strategy is to administer a factional dose of eIPV intradermally. Twenty percent of the standard eIPV dose given intradermally results in lower antibody titers than does the full dose intramuscular eIPV but, depending on vaccination timing, can achieve comparable seroprotection rates. One study evaluating a booster of 40% dose intradermal eIPV versus full-dose intramuscular eIPV showed comparable antibody titers and immunity levels.[25] Other strategies to reduce the cost of eIPV are being studied, including intradermal eIPV patches, adjuvanted eIPV, and optimization of the eIPV production process.[34]

Enhanced-Potency Inactivated Poliovirus Vaccine, Oral Poliovirus Vaccine, and the

Poliomyelitis Eradication End Game

The role of eIPV versus OPV for routine immunization is reassessed frequently. When given in a 3-dose schedule, both vaccines provide lifelong serologic immunity for a majority of recipients. OPV results in better mucosal immunity, a feature that could help prevent the spread of polioviruses in the community.[35] OPV also can boost immunity in contacts of recipients through spread of the vaccine virus. In addition, OPV is significantly less expensive than IPV, costing $0.15 versus $2.50 per dose.[34] However, OPV alone is less likely to provide adequate immunity in certain tropical countries. Furthermore, OPV carries an attendant risk of both VAPP and VDPV. In 2012, more cases of paralytic poliomyelitis were caused by VAPP and VDPV globally than were caused by wild polioviruses.[36] Consequently, to achieve poliomyelitis eradication, OPV will need to be phased out.

The *Polio Eradication and Endgame Strategic Plan 2013–2018* produced by the World Health Organization is a coordinated plan to phase out the use of OPV.[36,37] It first recommended universal eIPV introduction (≤1 dose in all countries) in the fall of 2015, followed by a synchronized transition from trivalent OPV to bivalent OPV (containing only serotypes 1 and 3) in April 2016. The eIPV dose is recommended to provide some level of serotype 2 immunity to protect against circulating serotype 2 vaccine viruses (serotype 2 wild poliovirus has been eradicated). The switch to bivalent OPV would help remove serotype 2 vaccine virus from circulation to prevent new VDPV cases because most VDPV has been serotype 2. The strategic plan then recommends cessation of the use of bivalent OPV 3 years after wild poliovirus is last detected.

Current Poliovirus Immunization Schedule in the United States

Because of the absence of indigenous transmission of wild-type poliovirus in the US and the rare but continued occurrence of VAPP in the 1990s, the US Public Health Service recommended a sequential 2-dose eIPV–2-dose OPV vaccination schedule from 1997 through 1999.[26] Since January 2000, immunization has consisted of a

4-dose series of eIPV exclusively: at 2, 4, and 6 to 18 months and 4 to 6 years (see Chapter 6). The change to eIPV resulted in the elimination of VAPP in the US, without a negative impact on vaccine coverage.

In the US, OPV has not been used since 2000, but it could be implemented by public health officials for mass vaccination in the event of a poliomyelitis outbreak. Travelers to countries where OPV is used, who are previously unimmunized, or who have not received a booster dose of IPV should be aware of the risk of VAPP in these settings and should consider IPV immunization. Travelers who have received an incomplete series should complete the series, not repeat it. For previously immunized adult travelers to poliomyelitis-endemic areas, vaccination with 1 dose of IPV is recommended; for adult travelers who have not previously been immunized, 3 doses of IPV should be given with intervals of at least 4 weeks between doses.[38] Available information suggests that only 1 lifetime booster dose of IPV is necessary. Current information regarding poliomyelitis-endemic areas can be obtained at www.polioeradication.org, and updated poliovirus immunization information can be obtained at www.cdc.gov.

Author Note

The content in this chapter solely represents the opinions of the authors and does not represent the opinion of the US Food and Drug Administration.

Key Points

Epidemiology, Diagnosis, and Management of Poliovirus Infections

Microbiology

- Positive-stranded RNA viruses belonging to the Picornaviridae family
- Three antigenically distinct serotypes

Epidemiology

- Humans are the only known natural host.

- Transmission is primarily by the fecal-oral route.

- Polioviruses are highly contagious.

- At its peak, 600,000 cases/year occurred, but vaccination has decreased the incidence by >99%, and global eradication is within reach.

Clinical Features

- Most infections are asymptomatic.

- In <1% of infections, paralysis ensues, characterized by asymmetric paralysis affecting proximal more than distal muscles and lower more than upper extremities.

- Bulbar paralysis, occurring in 5% to 35% of paralytic cases, is the most severe form; death usually results from respiratory compromise.

- Sensory abnormalities are rare.

Diagnosis

- Isolation of virus from a clinical specimen, usually stool.

Treatment/Prevention

- Treatment is supportive.

- Both a live, attenuated oral poliovirus vaccine (OPV) and an inactivated poliovirus vaccine (IPV) are used globally and are highly effective; IPV is used exclusively in the United States.

Enteroviruses and Parechoviruses

Kevin Messacar, John F. Modlin, Mark J. Abzug

The human enteroviruses and parechoviruses are members of the Picornaviridae family that are commonly transmitted by enteric and respiratory routes and cause a wide spectrum of illnesses in people of all ages.

The enteroviruses are divided among 4 species within the genus *Enterovirus, human enterovirus A, B, C,* and *D,* based on RNA sequence relatedness. *Enterovirus species C* polioviruses and 3 additional genus *Enterovirus* species, *human rhinovirus A, B,* and *C,* are discussed in separate chapters. Before the availability of viral genome sequencing, the human enteroviruses were distinguished from the rhinoviruses by their relative acid stability and were subdivided into several classes based on differences in host range and into individually numbered serotypes within each class on the basis of differential neutralization by immune sera (Table 236.1). The 3 poliovirus serotypes are the prototypic enteroviruses that can be transmitted to nonhuman primates and replicate in primate cell culture. The coxsackieviruses originally were distinguished from polioviruses by their ability to cause paralysis and death in suckling mice. They are divided into groups A and B according to the type of disease produced in these animals (see Table 236.1). Group B coxsackieviruses are isolated readily in primate cell culture, whereas most group A coxsackieviruses grow poorly in cell culture. Echoviruses (enteric cytopathic human orphan viruses) are not pathogenic for mice and monkeys but are recovered readily in primate cell culture. All enterovirus serotypes identified since 1970 are designated simply as enterovirus and are numbered sequentially. More than 100 poliovirus, group A coxsackievirus, group B coxsackievirus, echovirus, and enterovirus serotypes are now distributed among the 4 *human enterovirus species A* through *D* (Table 236.2).

TABLE 236.1

Traditional Biologic Classification of the Human Enteroviruses

Subgroup	Serotypes	Experimental Host Range		Cell Culture
		Primates	Newborn Mice	
Polioviruses	1–3	++	–[a]	++
Coxsackievirus A	1–24[b]	–[c]	+++	±[d]
Coxsackievirus B	1–6	–	+++	++
Echoviruses	1–34[e]	–	–[f]	++
Enteroviruses	68–72[g]	Variable	Variable	+

[a] Rare strains (e.g., Lansing strain of poliovirus 2) have been adapted to mice.

[b] Coxsackievirus A23 has been reclassified as echovirus 9, which leaves 23 coxsackieviruses in group A. Antigenic interrelationships exist between coxsackievirus types A3 and A8, A11 and A15, and A13 and A18.

[c] Coxsackievirus A7 is pathogenic for the central nervous system of primates.

[d] Most coxsackievirus serotypes of group A are not readily isolated in cell cultures, but exceptions exist (e.g., types A9 and A16), and additional serotypes have been adapted to cell cultures.

[e] Echovirus 10 has been reclassified as reovirus 1 and echovirus 28 as rhinovirus 1A. Echovirus 34 is a variant of coxsackievirus A24; a total of 31 serotypes of echovirus therefore remain from the original 34. Antigenic interrelationships exist between echovirus types 1 and 8, 12 and 29, and 6 and 30. Echoviruses 22 and 23 are now reclassified in the genus *Parechovirus*.

[f] Except echovirus 21.

[g] Hepatitis A virus was designated as enterovirus 72 but now is classified as a separate Picornavirus genus.

TABLE 236.2

Classification of Human Enteroviruses by RNA Sequence

Enterovirus Species	Enterovirus Serotypes
A	Coxsackievirus A serotypes 2–8, 10, 12, 14, 16
	Enterovirus serotypes 71, 76, 89–91, 114, 119, 120, 121
B	Coxsackievirus A serotype 9

	Coxsackievirus B serotypes 1–6
	Echovirus serotypes 1–7, 9, 11–21, 24–27, 29–33
	Enterovirus serotypes 69, 73–75, 77–88, 93, 97, 98, 100, 101, 106, 107, 111
C	Coxsackievirus A serotypes 1, 11, 13, 17, 19–22, 24
	Poliovirus serotypes 1–3
	Enterovirus serotypes 95, 96, 99, 102, 104, 105, 109, 113, 116–118
D	Enterovirus serotypes 68, 70, 94, 111

Adapted from Picornavirus Taxa. http://www.picornastudygroup.com/taxa/taxa.htm.

Parechoviruses share many of the same biologic, clinical, and epidemiologic characteristics as enteroviruses, but they differ sufficiently in genomic sequence to be classified in a separate genus.[1] The prototypic parechovirus serotypes 1 and 2 originally were designated echovirus 22 and 23, respectively; 14 human parechovirus serotypes are recognized currently.

Pathogenesis

The pathogenesis of enterovirus infections has been investigated most extensively with poliovirus infection in monkeys and humans. Although comparable data are not available for the nonpolio enteroviruses, it is assumed that the pathogenic events are similar, although tissue and organ tropism is highly variable. Enterovirus D68 differs from other human enteroviruses in that it is primarily an agent of respiratory disease, sharing biologic and molecular properties with human rhinoviruses, and therefore is discussed separately at the end of this section.

Human enteroviruses are acquired directly or indirectly by the ingestion of virus that is shed in the feces or upper respiratory tract of infected contacts. Initial viral replication occurs in the upper respiratory tract and distal small bowel. Infectious virus is detectable in ileal lymphoid tissue 1 to 3 days after the ingestion of virus, and fecal shedding can be detectable for ≥6 weeks. Generally, enteroviruses are recovered from the gastrointestinal tract in greater density and for longer periods than from the upper respiratory tract, with the exception of enterovirus D68.

Viral replication in submucosal lymphoid tissue gives rise to a transient "minor" viremia that distributes virus to reticuloendothelial tissue in distant lymph nodes, liver, spleen, and bone marrow. Early viral replication does not cause histopathologic changes in the gastrointestinal tract or lymphoreticular tissue.

Further replication in these organs leads to a sustained “major” viremia and dissemination of virus to target organs such as the central nervous system (CNS), heart, and skin.

Many infected people control infection before major viremia and experience only transient symptoms or have asymptomatic infection. The onset of symptomatic disease including fever and other systemic manifestations coincides with major viremia, and organ-specific disease (i.e., poliomyelitis, myocarditis) is determined by tropism of the infecting serotype. Disease results from virus-induced cell necrosis and the accompanying inflammatory response. For example, animal models of myocarditis demonstrate initial viral replication in myocytes that results in scattered necrosis and focal infiltration with inflammatory cells that persists for weeks to months after disappearance of virus. The late phase of the inflammatory response is postulated to be caused by virus-induced, cytotoxic T-lymphocyte destruction of myocytes, development of a myocardial neoantigen,[2] or cross-reactivity between viral and myocardial cell antigens.[3] Healing is accompanied by interstitial fibrosis and loss of myocytes. Both experimental and clinical data suggest that certain host factors enhance the severity of enterovirus infection, including exercise during the incubation period, cold stress, malnutrition, and B-lymphocyte immunodeficiency.

Enterovirus D68 is isolated most frequently from respiratory specimens rather than fecal samples. Enterovirus D68 grows most efficiently at 33°C (rather than at 37°C, as do other enteroviruses) and is acid sensitive, a feature that can limit survival in the gastrointestinal tract.[4] Primarily spread through respiratory transmission, enterovirus D68 attaches to sialic acid receptors on epithelial cells of respiratory mucosal surfaces.[5] Enterovirus D68 has been detected in serum from children with pneumonia early in the course of illness,[6] as well as in the CNS in case reports.[7,8]

Immunity

Protective immunity to enterovirus infection is serotype specific. Infection leads to production of neutralizing humoral antibodies that protect against recurrent disease but not against asymptomatic reinfection. Passive antibody provided by immune globulin,[9] or by transplacental maternal antibody,[10] effectively prevents enterovirus disease. Secretory immunoglobulin A (IgA) antibodies appear in nasal and duodenal secretions 2 to 4 weeks after primary infection and persist for at least 15 years.[11] Secretion of IgA antibodies at each mucosal site depends on local virus replication.[12] On enterovirus re-exposure, secretory IgA antibodies prevent or substantially reduce subsequent replication. Secretory IgA antibodies also are found in colostrum and milk of immune women. Antibodies in human milk can interfere with the replication of attenuated polioviruses given to breastfed infants during the first month of life.[13]

Patients with isolated B-lymphocyte immunodeficiency syndromes develop persistent enterovirus infections, a finding suggesting that humoral antibodies are necessary for viral clearance.[14] Administration of intramuscular immune serum globulin does not affect the course of acute poliovirus poliomyelitis,[15] but few controlled trials of immune globulin intravenous (IGIV) in other CNS and non-CNS enterovirus infections have been performed. Studies in a well-characterized murine model showed that inhibition of T-lymphocyte function has little effect on the course of enterovirus infection, although T lymphocytes participate in immunopathologic events contributing to the cytotoxicity that accompanies infection.[16] These data may explain the observation that patients with T-lymphocyte immunodeficiency or immunosuppression appear to be at lesser risk for severe or prolonged enterovirus infection. In contrast, experimental studies suggested that macrophage function is critical to clearance of virus and recovery from infection.[17] Other host factors, including human leukocyte antigen (HLA) genes, immune response gene polymorphisms, and vitamin A deficiency are linked to susceptibility and severity of enterovirus A71 disease.

Epidemiology

Infections occur in all human populations, although rates of infection vary markedly by geography, season, age, and other host factors. Transmission occurs throughout the year in most locations, but at much higher rates in temperate climates in summer and fall.[18] Seasonal periodicity is more pronounced (i.e., higher density of infection during short seasons) with increasing latitudes in both hemispheres compared with tropical latitudes. Conversely, seasonal fluctuations diminish in tropical latitudes.

Although enterovirus infections and disease occur in all age groups, infants and young children have the highest rates. Infants <1 year of age are infected at severalfold higher rates than children and adults; and within the first year of life, enterovirus infections are recognized most often clinically in infants <3 months of age.[19–21] The risk of disease in boys exceeds that in girls by as much as 50%. Infants of low socioeconomic status have a higher risk of infection that is attributable to crowding and poor hygiene.

The contribution of different enterovirus serotypes to human infection and disease varies markedly. Thirty percent to 80% of adults have antibody to the more common enterovirus serotypes (e.g., group B coxsackieviruses 1 to 5 and some echoviruses). A few serotypes cause endemic disease with annual regional variation in the United States. Other serotypes (e.g., echoviruses 9, 11, and 30) are responsible for widespread outbreaks in which the epidemic strain accounts for >30% of all isolated enteroviruses, followed by several years of relative quiescence.[22] The reasons for the appearance and disappearance of particular serotypes are unknown, although accumulation of a “critical mass” of susceptible young children may be necessary to sustain epidemic transmission.[23] Periodic reappearance of the same serotype is marked by strain variation as measured by oligonucleotide fingerprinting or genomic sequencing.[21,24] Between 1970 and 2008, species B enteroviruses predominated among enterovirus isolates submitted from state and local public health laboratories to the National Enterovirus Surveillance System (NESS) of the Centers for Disease Control and Prevention.[25,26] From 2006 to 2008, 8 serotypes (all species B enteroviruses) represented 72% of all enteroviruses submitted to the NESS (Table 236.3).[25] In contrast, some enterovirus serotypes (e.g., echovirus 1, coxsackievirus B6, and enterovirus B69) rarely are recognized clinically and appear to have little epidemic potential.

TABLE 236.3

Most Common Enterovirus Serotypes Submitted by State and Local Public Health Laboratories to Centers for Disease Control and Prevention, 2006 to 2008

Enterovirus Serotype	Percentage
Coxsackievirus B1	16.5
Echovirus 6	10.7
Echovirus 9	10.7
Echovirus 18	8.8
Coxsackievirus A9	7.5
Coxsackievirus B4	6.7
Echovirus 11	5.8
Coxsackievirus B3	5.4
Total	72

From Centers for Disease Control and Prevention. Nonpolio enterovirus and human parechovirus surveillance—United States, 2006–2008. MMWR Morb Mortal Wkly Rep 2010;59:1577–1580.

Enterovirus A71 has caused large outbreaks of hand-foot-and-mouth (HFM) disease, aseptic meningitis, and serious CNS disease in young children.[27–37] Although sporadic cases and small outbreaks of enterovirus A71 infections occur globally, since the mid-1990s several genetic lineages, most recently genotype C4, have caused widespread disease in infants and young children throughout Asia.[38–46]

Enterovirus D68 was uncommonly reported to the NESS from 1970 to 2008. From 2008 to 2010, small regional outbreaks of enterovirus D68 were reported in Asia, Europe, and the US.[47] In 2014, the largest and most widespread outbreak of enterovirus D68 respiratory disease occurred in the US, with more than 1100 confirmed infections.[48]

Transmission

Enteroviruses are shed in the upper respiratory tract for 1 to 3 weeks and in the feces for 2 to 8 weeks after primary infection, findings suggesting both respiratory and fecal-oral routes of transmission. Studies of naturally occurring and attenuated polioviruses demonstrate that fecal (but not oropharyngeal) shedding also occurs during reinfection, albeit at lower titer and for a shorter duration. Both direct fecal-oral and indirect mechanisms of person-to-person transmission are postulated. Secondary infection rates exceed 50% in household contacts.[49] Infants, particularly those in diapers, appear to be the most efficient transmitters of infection. Indirect transmission is abetted by poor sanitary conditions and can occur by numerous routes, including contaminated water, food, and fomites. The relative roles of virus shedding by symptomatic and asymptomatic people are not known, but both are likely important. Notable exceptions to the importance of respiratory and fecal-oral transmission are enterovirus D70 and coxsackievirus A24, the agents of acute hemorrhagic conjunctivitis, which are shed in tears and spread by fingers and fomites.[50]

The incubation period for enteroviral infection is difficult to determine precisely and may vary according to the clinical syndrome. Brief febrile illnesses occur after an average incubation period of 3 to 5 days. Detailed studies of poliovirus infection have indicated that CNS manifestations (i.e., aseptic meningitis, poliomyelitis) usually are not observed until 9 to 12 days after exposure.[51] The incubation period of acute hemorrhagic conjunctivitis is 1 to 3 days.

Clinical Manifestations

Most enterovirus infections in children are asymptomatic. The proportion of infections that result in illness varies widely and is affected by numerous host factors. Table 236.4 shows clinical syndromes commonly associated with nonpolio enterovirus infections in children. Some enteroviral diseases (e.g., nonspecific febrile illness, pharyngitis, and aseptic meningitis) are associated with multiple serotypes of group B coxsackievirus and echovirus,[49,52] whereas others are associated with specific subgroups (e.g., myopericarditis with group B coxsackieviruses and herpangina with group A coxsackieviruses) or a limited number of serotypes (e.g., acute hemorrhagic conjunctivitis with coxsackievirus A24 or enterovirus D70).

TABLE 236.4

Spectrum of Illness Caused by the Enteroviruses

	Group A Coxsackieviruses	Group B Coxsackieviruses	Echoviruses	Newer Enteroviruses
EXANTHEMS AND ENANTHEMS				
Herpangina	+++	+	+	−
Hand-foot-and-mouth disease	+++	+	−	+++
Nonspecific rash	++	+	+++	++

CENTRAL NERVOUS SYSTEM INFECTIONS

+++, characteristic; ++, occasionally reported; +, rarely reported; −, no known association.

Nonspecific Acute Febrile Illnesses

Nonpolio enteroviruses are the most commonly identified causes of fever without an apparent focus in infants <3 months of age.[53,54] During the summer and fall, enteroviruses account for at least one half of cases.[20,21,55] Fever often occurs alone or in association with irritability, lethargy, poor feeding, vomiting, diarrhea, exanthems, or signs of upper respiratory tract infection.[56] Approximately one half of infants infected with an enterovirus have aseptic meningitis,[54,56] often in the absence of meningeal signs.[56] Most infants with fever or aseptic meningitis recover within 2 to 10 days without complications.

Exanthems and Enanthems

Enteroviruses are common causes of a broad array of acute cutaneous eruptions and mucous membrane lesions (Fig. 236.1). Exanthems can be maculopapular and resemble those of measles, rubella, or roseola, or they can be vesicular, petechial, purpuric, or urticarial. Exanthems are reported more commonly with echovirus infections than with infections with other enteroviruses.

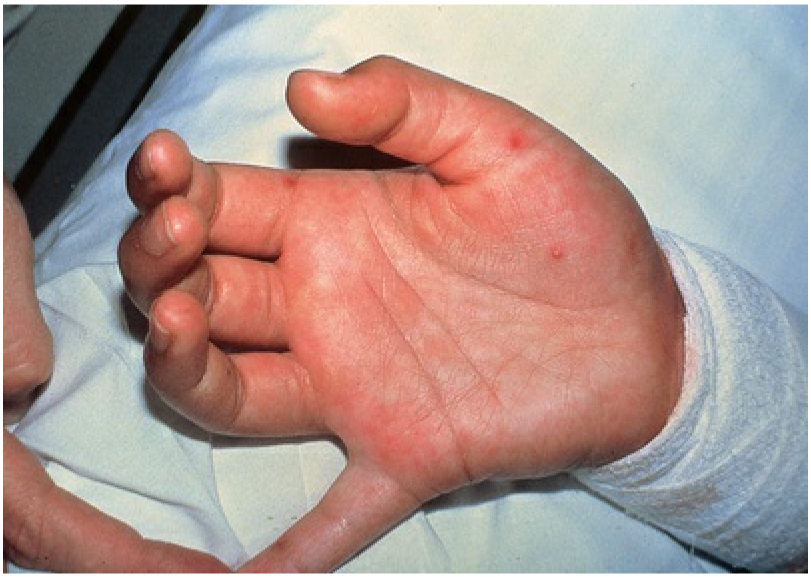

FIGURE 236.1 **Typical hand lesions of Coxsackie A virus in an infant with a febrile illness. No other exanthem was present.** (Courtesy of M. C. Fisher and S. S. Long, St. Christopher's Hospital for Children, Philadelphia.)

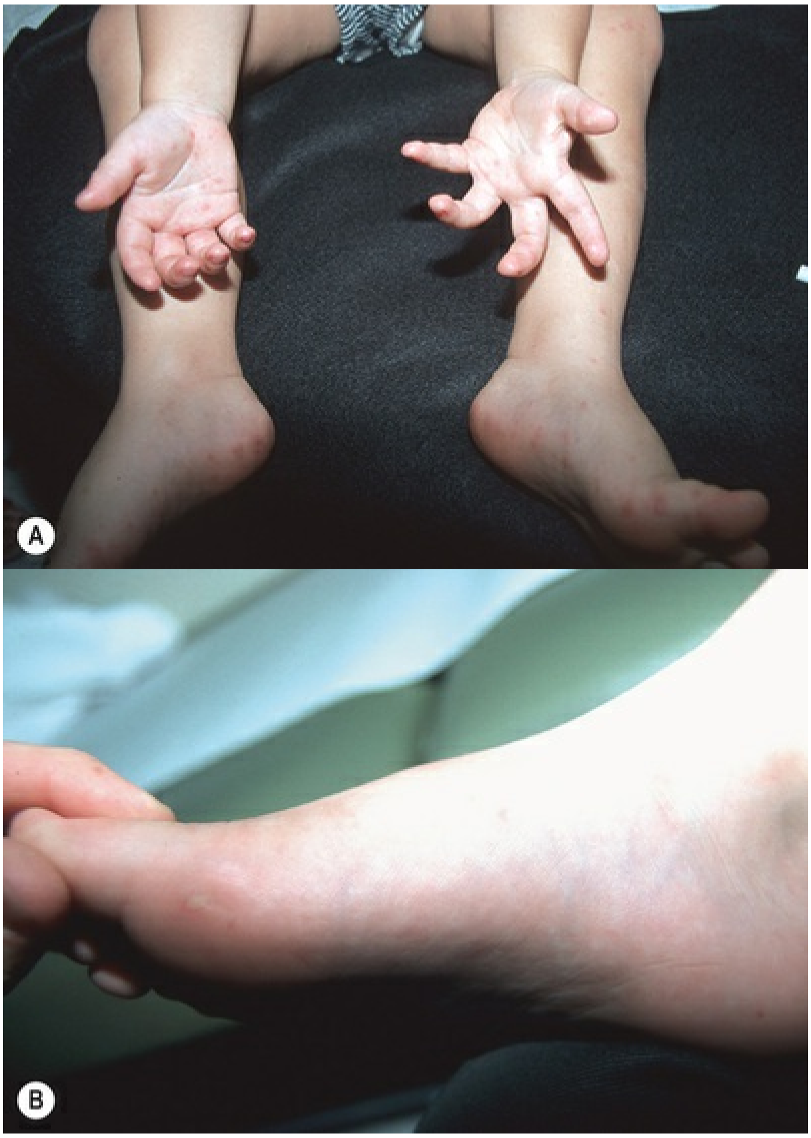
Herpangina is a distinctive enanthem characterized by painful vesicular lesions on the soft palate, uvula, tonsils, and posterior oropharynx, often accompanied by fever, headache, and sore throat. Mucosal lesions begin as punctate macules and evolve over a 24-hour period to 2- to 4-mm vesicular lesions that ultimately ulcerate centrally. Fever subsides in 2 to 4 days, but lesions can persist for a week.

Coxsackievirus A6 and coxsackievirus A16 (and less commonly other group A and group B coxsackieviruses) and enterovirus A71 cause *HFM disease*, a syndrome characterized by vesicular stomatitis and cutaneous lesions of the distal extremities (Fig. 236.2). Children <10 years of age are affected most commonly. Fever, sore throat, and refusal to eat are common complaints. Oral lesions occur chiefly on the buccal mucosa and tongue and can coalesce and ulcerate by the time of the initial examination. Cutaneous lesions occur in approximately 75% of cases and are found mainly on the hands, feet, wrists, ankles, and buttocks or genitalia. HFM disease associated with coxsackievirus A6 can be extensive and additionally can involve perioral, perianal, and dorsal hand and feet lesions.[57] The lesions of HFM disease typically are tender papules or vesicles with a surrounding zone of erythema; vesiculobullous, purpuric, and Gianotti-Crosti–like lesions and lesions accentuated in areas of eczematous dermatitis have been associated with coxsackievirus A6.[58] HFM disease generally is self-limited, with an average 7-day duration.[55] When caused by enterovirus A71, however, HFM disease can herald the onset of more serious CNS disease, including acute motor neuron disease and brainstem encephalitis.[38,59,60]



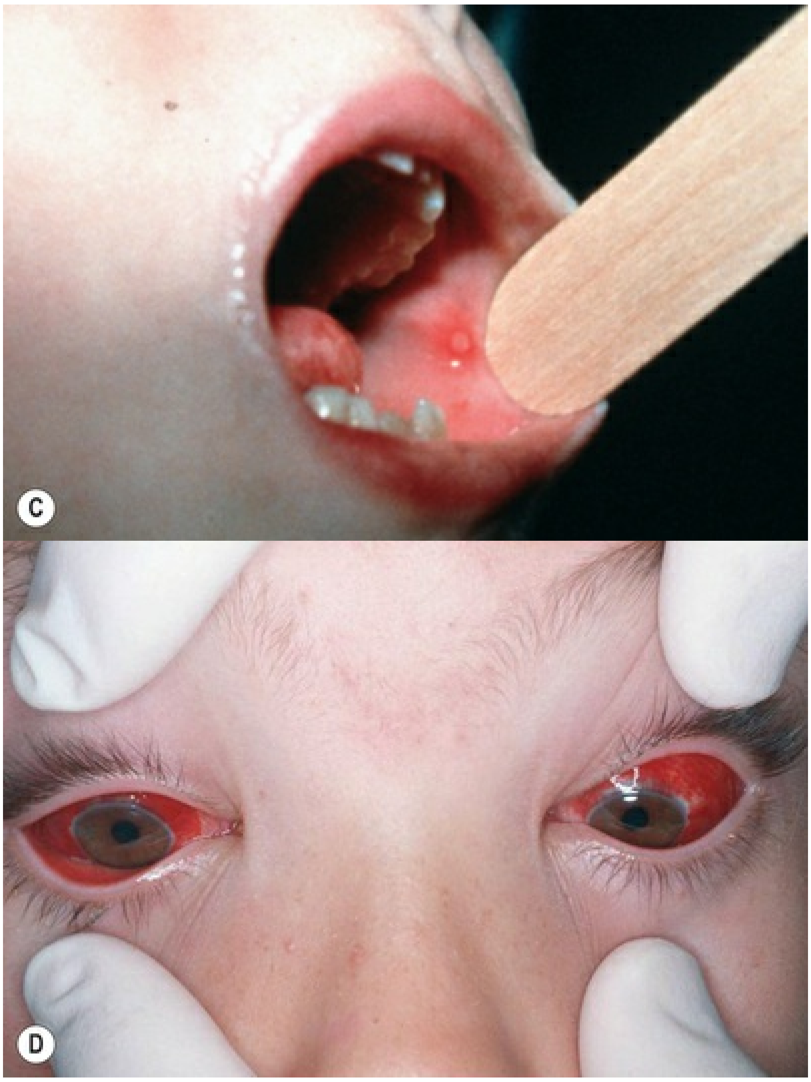


FIGURE 236.2 Characteristic findings of hand, foot and mouth disease include (A, B) petechial, maculopapular, or vesicular lesions on hands and feet and (C) ulcerative lesions with erythema on the oral mucosa. (D) Acute hemorrhagic conjunctivitis with hemorrhage and edema of the conjunctivae. (Copyright by J. H. Brien.)

Respiratory Infections

Sore throat and coryza are frequent upper respiratory tract symptoms associated with the early phase of many enterovirus infections. Acute parotitis occasionally is reported in association with herpangina caused by group A coxsackieviruses and also with group B coxsackieviruses and enterovirus D70 infections. Exudative pharyngitis, otitis media, croup, bronchiolitis, and pneumonia are other less common respiratory findings associated with some enteroviruses.

Enterovirus D68 is associated primarily with respiratory disease. Although most enterovirus D68 infections are associated with mild respiratory symptoms, severe lower respiratory disease leading to hospitalization, intubation, and death is reported. Among children hospitalized with enterovirus D68 respiratory infection, one half had a history of asthma. Most of these children presented with dyspnea, cough, wheezing, tachypnea, and hypoxia, and approximately 50% were febrile.

Central Nervous System Infections

Meningitis

Most cases of community-associated aseptic meningitis are caused by viruses, 90% of which are group B coxsackieviruses and echoviruses.[52] Although many serotypes cause meningitis, coxsackievirus serotypes B2 and B5 and echovirus serotypes 4, 6, 9, 11, 16, and 30 are most commonly reported. Not all enteroviruses that infect young infants are equally likely to cause meningitis. In 1 study, febrile infants infected with certain serotypes (e.g., the group B coxsackieviruses and echovirus serotypes 11 and 30) were more likely to have meningitis; group A coxsackieviruses caused <5% of cases.[56] Enterovirus D68 has been detected in cerebrospinal fluid (CSF) in case reports of aseptic meningitis.[61]

Infants <3 months of age appear to have the highest rate of aseptic meningitis, perhaps in part because lumbar puncture commonly is performed for evaluation of fever in this age group.[20] A few infants have clinical manifestations suggestive of neurologic disease.[20,55,56] The severity of meningeal symptoms and other signs of neurologic involvement in older children and adults with aseptic meningitis varies widely. Onset can be gradual or abrupt. Typically, the patient has a brief prodrome of fever, chills, and headache. Meningismus, when present, varies from mild to severe. Kernig and Brudzinski signs are present in only one third of older children and adults.

The CSF white blood cell (WBC) count can be normal or demonstrate mild pleocytosis (typically <500 WBCs/μL but occasionally >1000 WBCs/μL). Pleocytosis frequently is predominantly polymorphonuclear in the first 48 hours, then transitioning to mononuclear prominence. CSF glucose typically is normal (10% <40 mg/dL), and CSF protein is normal to mildly elevated (<100 mg/dL).

Most cases of enteroviral meningitis are uncomplicated. Fever and signs of meningeal irritation resolve in 2 to 7 days, but CSF pleocytosis can persist. A biphasic pattern of illness can occur, with fever in the initial phase followed by return of fever and meningeal signs after several days of an afebrile interlude. Adults compared with children appear to have more severe and prolonged symptoms.[62] Approximately 10% of infants hospitalized with aseptic meningitis experience acute CNS complications such as seizures, obtundation, or increased intracranial pressure.[20,63] Although some early reports suggested that infants with viral meningitis at an early age had a moderate risk of longterm neurologic and cognitive sequelae,[64] prospective studies have indicated no measurable effect,[65,66] including infants with neurologic findings during the acute illness.[20]

Encephalitis

Enteroviruses are among of the most commonly identified causes of infectious encephalitis; these viruses account for ≥10% to 20% of cases of known origin. Many nonpolio enterovirus serotypes have been identified in patients with encephalitis. Group A coxsackieviruses have been isolated from infants and children with focal enteroviral encephalitis.[67]

Clinical manifestations of enterovirus encephalitis range from mild, reversible changes in mental status to coma, decerebration, and death. Patients with focal encephalitis can have partial motor seizures, hemichorea, or acute cerebellar ataxia. Initial findings in some cases suggest a diagnosis of herpes simplex virus encephalitis.[67,68] Because CSF findings in enteroviral encephalitis are similar to those of aseptic meningitis, the term *meningoencephalitis* commonly is used interchangeably with *encephalitis.* Magnetic resonance brain imaging and electroencephalography usually reflect the extent and severity of disease. Encephalitis occurring as a manifestation of generalized neonatal infection (see the later section on infection in special hosts) often is fatal or results in permanent neurologic sequelae. The prognosis for older infants and children is better; although static neurologic sequelae and rare deaths occur, most patients recover fully.

Poliomyelitis-Like Illness

Nonpolio enteroviruses uncommonly cause a syndrome of acute motor weakness and acute flaccid paralysis (AFP) that is clinically and pathologically indistinguishable from poliomyelitis. Outbreaks of acute paralysis caused by enterovirus A71 have involved thousands of people, mostly children, in Eastern Europe and Asia, as well as smaller numbers of patients in Australia and parts of the US.[60,69–71] Coxsackievirus A7 has caused small outbreaks of AFP in Scotland and Russia, and AFP has been described in enterovirus D70 epidemics. Sporadic cases of AFP can be caused by numerous enteroviruses, most commonly the following: enterovirus A71; group A coxsackievirus types 7, 9, and 24; group B coxsackievirus types 1 to 5; and echovirus types 6 and 9. The myelitis caused by nonpolio enteroviruses tends to be less severe than that caused by polioviruses (i.e., less persistent muscle weakness and less common bulbar involvement).

Cases of acute flaccid weakness and cranial nerve dysfunction in children temporally associated with an outbreak of enterovirus D68 respiratory disease were noted in the US and, to a lesser extent, in Europe and Canada in 2014.[72–75] The term *acute flaccid myelitis* was used to describe the acute onset of limb weakness associated with neuroimaging lesions in the grey matter of the spinal cord.[76] Most children had abrupt onset of neurologic deficits approximately 1 week following an acute febrile respiratory illness. Preceding or concurrent headache, neck stiffness, photophobia, and pain in the affected limb, neck, or back were common. Cranial nerve dysfunction was seen in 34% of cases and was associated with focal lesions in cranial nerve nuclei in the brainstem. Limb weakness commonly was asymmetric and was associated with hyporreflexia and intact sensation of the affected limb, similar to findings in poliomyelitis. Mild improvements in neurologic deficits were reported, but residual weakness persisted in most cases. In some children with acute flaccid myelitis, enterovirus D68 was identified in respiratory samples, but not in the CSF, thus precluding causal attribution.

Brainstem Encephalitis

A distinctive, life-threatening form of brainstem encephalitis has been observed during epidemics of enterovirus A71 infection in Malaysia, Australia, Taiwan, China, and other locations.[38,39,60,71] Most cases occur in children <5 years of age and in association with HFM disease or herpangina. Affected children have myoclonus, vomiting, ataxia, nystagmus, and oculomotor palsies. The most severely affected patients die rapidly of noncardiogenic pulmonary edema, pulmonary hemorrhage, interstitial pneumonitis, or cardiac dysfunction, postulated to be caused by dysregulation of sympathetic outflow and overload of the pulmonary vascular bed.[60,77] High rates of neurologic sequelae occur among survivors of severe disease. Neuronal degeneration and mononuclear cell infiltration in the grey matter of the pons and medulla are found at postmortem examination; enterovirus A71 has been isolated from brainstem tissue, but uncommonly from CSF.[39,71] A few similar cases have occurred sporadically in the US.[27,78]

Other Neurologic Syndromes

Guillain-Barré syndrome is reported in a limited number of patients infected with group A coxsackievirus types 2, 5, and 9 and echovirus types 6 and 22. Acute transverse myelitis has been attributed to coxsackievirus A9, coxsackievirus B4, and echovirus 5.

Infections of Skeletal and Cardiac Muscle

The myotropic nature of the group A and group B coxsackieviruses has been recognized since their discovery. Group B coxsackievirus types 1 to 5 are the principal causes of myotropic diseases, although pleurodynia and myopericarditis rarely have been associated with some group A coxsackieviruses and echovirus types.

Pleurodynia (Epidemic Pleurodynia, Bornholm Disease)

Pleurodynia, an acute, communicable disease involving the intercostal and abdominal muscles, is characterized by fever and sharp, spasmodic pain in the chest wall or abdomen. Local outbreaks of pleurodynia with high attack rates within affected households have occurred, and major epidemics can take place every 10 to 20 years. The diagnosis of pleurodynia is more common in older children and adults. Involvement of the abdominal muscles is more common in younger children than in older children and adults, who most often have thoracic pain. The paroxysmal nature of the pain is a hallmark of the disease. Involvement of the intercostal and other muscles of respiration enhances pain with deep breathing and causes a sensation of “pleuritic” pain that can result in splinting of the chest and rapid, shallow breathing. Muscle inflammation can be detected by eliciting tenderness on direct palpation or, less commonly, by observing localized swelling. Fewer than 10% of patients have a pleural friction rub or pleural fluid evident on chest radiographs. Pain is most severe initially and typically diminishes over 4 to 6 days, although pain can persist up to 3 weeks. Illness can be biphasic. Analgesic medications and limitation of physical activity are helpful in reducing pain.

Myositis

Involvement of other muscles is less common; sporadic cases are caused by coxsackieviruses A9, B2, and B6 and by echoviruses 9 and 11. Both focal and generalized myositis can occur. Focal myositis often involves the thigh muscles. Generalized myositis frequently manifests as polymyositis syndrome with an abrupt onset of fever, chills, and weakness, tenderness, and edema of the involved muscle groups. Myoglobinemia, myoglobinuria, and elevated serum levels of skeletal muscle enzymes are characteristic. Most cases occur in adults, who recover rapidly.

Myopericarditis

Enteroviruses are major causes of acute infection of cardiac muscle and pericardium. Although most patients have symptoms and signs of either pericarditis or myocarditis, the term *myopericarditis* is preferred because pathologic studies reveal that both the pericardium and the myocardium usually are involved. Group B coxsackievirus types 2 to 5 account for one third to one half of sporadic cases,[79,80] and for almost all epidemic cases of myopericarditis,[81] but many other enterovirus serotypes have been implicated. Enteroviral myopericarditis is indistinguishable clinically from disease caused by other cardiotropic viruses.

Enteroviruses cause myopericarditis in all age groups. Physically active adolescents and young adults may have the highest risk, and male patients have at least twice the risk of female patients.[82] Approximately two thirds of patients have a febrile upper respiratory tract illness preceding symptoms of substernal chest pain, exercise intolerance, and dyspnea.[83] Auscultation reveals a pericardial friction rub in 35% to 80% of patients and a gallop rhythm or other signs of ventricular failure in ~20%. Electrocardiographic (ECG) abnormalities, including ST-segment changes, T-wave abnormalities, or arrhythmias, invariably are present. Echocardiography may confirm acute ventricular dilatation, diminished cardiac ejection fraction, or pericardial effusion. Serum levels of myocardial enzymes frequently are elevated. Although the acute course of myopericarditis often is complicated by congestive heart failure or cardiac arrhythmia, most children recover uneventfully. The mortality rate during the acute illness is <5%. However, ECG or echocardiographic abnormalities persist in 10% to 30% of patients, and similar proportions of patients have persistent or recurrent congestive heart failure.

Chronic dilated cardiomyopathy is the final result of multiple infectious and noninfectious cardiac insults,[84] including up to one third of cases of acute myopericarditis and, in some instances, unrecognized past enteroviral infection.[80,85,86] A case-control study of idiopathic dilated cardiomyopathy in adults in the United Kingdom and Italy suggested a possible association with group B coxsackieviruses.[87] Enteroviral RNA has been detected in cardiac tissue months to years after the onset of dilated cardiomyopathy in some studies,[88,89] but not in others using similar methods.[90–93]

Ophthalmic Infections

Acute hemorrhagic conjunctivitis is a highly contagious infection characterized by eye pain, eyelid swelling, and subconjunctival hemorrhage (see Fig. 236.2D). Widespread epidemics of acute hemorrhagic conjunctivitis have occurred in many parts of the world, particularly in the tropics. Two enterovirus serotypes have been responsible for almost all cases. Enterovirus D70 was the cause of the original pandemic in 1969 that spread globally during the early 1970s.[94] Since 1970, the epidemiology of disease caused by a variant of coxsackievirus A24 has intertwined with that of enterovirus D70.[95] Both viruses have caused epidemics throughout Southeast Asia and the Indian subcontinent. Disease in the West has been confined to seasonal outbreaks in the Caribbean, Central America, and southern Florida.[96]

Acute hemorrhagic conjunctivitis is transmitted directly from person to person by fingers and fomites. Both enterovirus D70 and coxsackievirus A24 are readily isolated from tears, but only infrequently from other sites. Contagion is favored by crowding and poor sanitation; reuse of water for bathing and sharing of towels contribute to the spread of infection. After an incubation period of 1 to 2 days, symptoms of ocular pain, photophobia, watery discharge, and swelling of the eyelids appear abruptly. Fever and headache occur in 20% of cases. The distinctive physical finding is subconjunctival hemorrhage, found in 70% to 90% of enterovirus D70 cases but in fewer coxsackievirus A24 cases. Conjunctival edema and follicle formation, punctate epithelial keratitis, and preauricular lymphadenopathy are present commonly. Symptoms and signs peak on the first day of illness and resolve within a few days without residual eye complications. Unusual cases of concomitant motor paralysis have been reported during some enterovirus D70 outbreaks.

Other Infections
